ABSTRACT

The Internet of Things (IoT) is an emerging paradigm where practically every (physical and virtual) thing will be interconnected through innovative distributed services. Since the number of connected things is rapidly growing, IoT systems will require the composition of plenty of services into complex workflows. Thus, scalability in terms of the size of IoT systems becomes a significant concern. In this paper, we review and evaluate the fundamental semantics of existing IoT service composition mechanisms to determine how well they fulfil the scalability requirements of IoT systems. We identify scalability desiderata and, accordingly, our findings show that dataflows, orchestration and choreography do not fully satisfy such desiderata, unlike a novel composition mechanism called DX-MAN.

1. Introduction

The Internet of Things (IoT) is an emerging paradigm that promises the interconnection of (physical and virtual) things through innovative distributed services. Like traditional enterprise services, IoT services interact in many different ways via the Internet, in order to realise a global system workflow. However, unlike traditional enterprise systems, IoT systems will require the interaction of billions of services as the number of connected things (and therefore services) is rapidly growing [1, 2]. Thus, scalability becomes a crucial concern.

Scalability is typically considered as a system capability to handle increasing workloads [3, 4, 5, 6, 7, 8]. In particular, vertical scalability [9, 10, 11] refers to the addition or removal of computing resources in a single IoT node, while horizontal scalability [2, 12, 13] involves the addition or removal of IoT nodes. These kinds of scalability have been addressed by an extensive body of research [4, 10, 11, 14, 15, 16, 17, 18, 19, 20], unlike scalability in terms of the number of services composed in an IoT system, which we refer to as functional scalability.

Existing service composition mechanisms were primarily designed for the integration of static enterprise services, not for the physical world. For that reason, they may not address the functional scalability challenges that IoT systems pose. Early IoT systems were deployed in closed environments, using private Application Programming Interfaces (APIs) and private data. However, future IoT systems will be deployed in open environments (also known as software ecosystems [21]) with an overwhelming number of available services, as a result of the huge number of connected things [22]. For that reason, billions of IoT services will be composed into complex IoT systems [23, 24, 25, 26, 27, 28]. This raises the challenging question of How to construct IoT systems composed of an ultra-large number of services?

In this paper, we study the ability of service composition mechanisms to handle any number of IoT services. Our aim is to determine which service composition mechanism best fulfils the functional scalability requirements of IoT systems. To answer this, we have reviewed the fundamental semantics (not specific implementation technologies) of existing composition mechanisms, and proposed an evaluation framework that considers six crucial desiderata: (i) explicit control flow [29, 30]; (ii) distributed workflows [23, 31, 32]; (iii) location transparency [20, 33]; (iv) decentralised data flows [23, 32, 34]; (v) separation of control, data and computation [35, 36, 37, 38]; and (vi) workflow variability [23, 39, 40, 41]. Our evaluation framework serves as a guideline for defining the semantics of future IoT service composition mechanisms.

The remainder of the paper is structured as follows. In the next section, we present an overview of IoT services, scalability and service composition. Section 3 outlines the related work on IoT service composition mechanisms. Section 4 introduces a motivating IoT scenario based on a smart parking system. The scenario is then considered in Section 5 to comprehensively describe the requirements for functional scalability and the rationale behind them. Section 6 analyses service composition mechanisms on the basis of the functional scalability requirements. Section 7 presents an evaluation that determines how well service composition mechanisms fulfil the scalability requirements. Our findings are then discussed in Section 8. Finally, Section 9 draws the conclusions and presents the directions for future research.

2. Background

This section presents a background for the rest of the paper, which includes an overview of IoT services, service composition and scalability.

2.1. IoT Services

Kevin Ashton coined the term Internet of Things (IoT) in a presentation made in 1999 at Procter and Gamble [42], referring to the interconnection of everything via the Internet for the creation of an ubiquitous computing environment [43]. As per the recommendation of ITU-T Y.4000, IoT has been

*Corresponding author.

† ORCID(s): 0000-0002-0074-390X (D. Arellanes)
recently redefined as “a global infrastructure for the information society, enabling advanced services by interconnecting (physical and virtual) things based on existing and evolving interoperable information and communication technologies” [44].

A thing is practically a physical or virtual construct of the real-world, which is capable of being identified and integrated into communication networks through specific protocols. The difference between physical and virtual things lies in their tangibility [45]. A physical thing is a tangible object of the physical world, which is capable of being sensed, actuated and connected, e.g., home appliances, robots, buildings, plants and people. Contrastingly, a virtual thing is a non-tangible construct formed from a human idea which only exists in the information world, e.g., Clouds and enterprises.

The broad range of available things inevitably requires dealing with a high degree of heterogeneity in a distributed environment. Accordingly, a Service-Oriented Architecture (SOA) represents the best way of dealing with this issue [46]. It is a logical way of designing a software system to provide services either to end-user applications or other services distributed in a network, via published and discoverable interfaces [47]. Thus, it is expected that physical and virtual things will provide services to expose behaviour via interfaces [5, 48, 49, 50, 51, 52].

According to the Oxford dictionary, the word service can be a noun or a verb referring to the action of helping or doing work for someone. Considering a service as a noun allows the encapsulation of behaviour (i.e., actions) in the form of operations described as verbs. Thus, a software service is a distributed software component that provides a set of operations through network-accessible endpoints [53, 54]. In general, IoT services are virtual representations of the behaviour of things, which can be combined with other services into more complex behaviours to yield complex service-oriented IoT systems [52, 55, 56, 57]. Thus, things are integrated through the composition of the services they provide (see Section 2.2).

Resource-constrained things (e.g., pulse sensors) typically provide fine-grained services for basic functionality (e.g., fetching sensor data), whilst non-resource constrained things (e.g., a Cloud) may offer coarse-grained services in addition (e.g., services for geolocation or complex industrial processes). Enterprise services are typically coarse-grained as they are deployed on resource-rich infrastructures, whilst services of physical things are often fine-grained because they are usually deployed on resource-constrained things.

Figure 1 shows the relationship between things, services and operations. Figure 1(a) depicts a washing machine (i.e., a resource-constrained physical thing) that offers the Washing and Drying fine-grained services with two operations each (for starting and stopping the respective processes). Figure 1(b) shows a City Council Cloud (i.e., a non-resource constrained virtual thing) that offers the services CouncilTax and Parking. The CouncilTax service provides the operations pay (to pay a tax bill) and check (to query council tax information). The Parking service offers the operations getNearest (for getting the closest parking space from a driver’s location) and registerDisabled (for registering an impaired driver).

For the rest of the paper, we use the notation $S.O$ to denote an operation $O$ in service $S$, e.g., Parking.getNearest refers to the getNearest operation provided by the Parking service.

### 2.2. IoT Service Composition Revisited

An IoT service is a distributed unit of composition, which constitutes the virtual representation of a thing’s behaviour, and can be either atomic or composite. An atomic service is a well-defined and self-contained piece of behaviour that cannot be divided into other services [58, 59, 60]. A composite service, on the other hand, is a more complex unit that provides value-added functionality and is formed by the combination of (atomic or composite) services [52, 55, 57, 58, 59, 61, 62]. For example, a humidity sensing service can be combined with a temperature service into an air conditioning composite [63].

The ability of combining services is referred to as compositionality and is realised by a composition mechanism [59]. Thus, an IoT system requires a things infrastructure, the definition of what a service is and the selection of a composition mechanism [64]. In any scenario, composition is done regardless of both the technologies being used and the things infrastructure. Service technologies include REST [65, 66], WS-* [67, 68], OSGi [69, 70] and many others.¹

A service composition mechanism defines a meaningful interaction between services [59] by considering two functional dimensions: control flow and data flow [71, 72]. Control flow refers to the order in which interactions occur [73, 74], whilst data flow defines how data is moved among services [71]. In this paper, we focus on service composition mechanisms that define behaviour by workflows, namely (centralised and distributed) dataflows, (centralised and distributed) orchestration, choreography, and a novel composition mechanism called DX-MAN. Section 6 provides a detailed description of these mechanisms.

A workflow describes a series of discrete steps for the realisation of a computational activity, which can be control-driven, data-driven or hybrid [75]. In a control-driven workflow, steps (also known as tasks [76], actors [77], transitions [78], procedures [79], thorns [80], activities [81] and units [82]) are executed according to explicit control flow constructs that define sequencing, looping, branching or parallelising. A data-driven workflow invokes steps whenever

¹In RESTful services, operations are exposed as resources [65].
data becomes available without explicitly defining any control flow constructs [83]. In a hybrid workflow, some parts are control-driven, while others are data-driven [82]. Figure 2 illustrates a generic workflow that executes the operation \( \text{op}_1 \), then decides to invoke either \( \text{op}_2 \) or \( \text{op}_3 \) and, finally, triggers the operations \( \text{op}_4 \) and \( \text{op}_5 \) in parallel. Operation invocations happen regardless of the workflow kind.

Figure 2: A generic workflow.

Workflows are increasingly important for IoT systems because they allow the integration of IoT services into complex tasks that automate a specific context [84, 85, 86, 87, 88]. For example, a smart home can be automated with a workflow that regulates the temperature of a room according to environmental changes. In the domain of smart agriculture, a workflow can be defined to analyse data coming from harvest sensors, predict diseases and react accordingly.

2.3. Scalability of IoT Systems

With the advent of hardware technologies, the number of IoT services is rapidly growing due to the excessive increase in the number of connected things. Currently, there are about 19 billion connected things, and it is predicted that this number will grow exponentially in the coming years [1, 2]. Thus, unlike traditional enterprise systems, scalability becomes a crucial concern for the full realisation of IoT systems.

Typically, scalability is the capability to handle increasing workloads in a IoT system [3, 4, 5, 6, 7, 8]. In this case, it is a metric that indicates how system performance improves over time. Workloads are typically measured in terms of either the number of requests dispatched [3] or the data streams generated [7]. The overall goal of scalable solutions is to enhance the Quality of Service (QoS) for guaranteeing a certain level of performance under the presence of high workloads, e.g., by minimising bandwidth, energy, latency and response time while maximising throughput. To quantitatively measure QoS, several network aspects of a service are considered such as jitter, throughput, packet loss and availability [8].

Currently, there are two kinds of scalability: vertical and horizontal. Vertical scalability (or scaling up) [9, 10, 11] refers to the addition or removal of computing resources in a single thing, e.g., adding more memory to increase buffer size or adding more processor capacity to speed up processing. On the other hand, horizontal scalability (or scaling out) [2, 12, 13] involves the addition or removal of things in an IoT system. Its goal is to distribute the workload over multiple things to decrease individual loads, minimise response time and enhance concurrency. Figure 3 depicts the contrast between vertical and horizontal scalability.

Figure 3: Scalability of IoT systems.

Both vertical and horizontal scalability have been extensively addressed in the literature [4, 10, 11, 14, 15, 16, 17, 18, 19, 20], unlike functional scalability which we refer to as the capability to accommodate growth in terms of the number of services composed in an IoT system (see Figure 3(c)). In particular, it enables the composition of any number of services, without severely impacting global system properties such as performance, maintenance, evolution and monitoring. Hence, functional scalability is crucial for dealing with IoT systems composed of billions of services. Figure 4 shows that it is orthogonal to vertical and horizontal scalability.

Figure 4: Scalability dimensions.

Like the other kinds of scalability, functional scalability requires the definition of metrics to measure the degree of satisfaction for accommodating new services. In this paper, we propose six qualitative metrics which we discuss in Section 5. We do not claim that such metrics are complete since quantitative metrics for QoS, identified for vertical and horizontal scalability, can also be important. However, quantitative metrics are only applicable to specific implementations. As service composition is an abstraction rather than a concrete implementation, we strongly argue that qualitative metrics are the best ones to measure the degree of satisfaction of functional scalability in service composition mechanisms. For the rest of the paper, the terms scalability and functional scalability are used interchangeably.
3. Related Work

This section presents the current IoT service composition mechanisms that define behaviour by workflows, namely (centralised and distributed) dataflows, (centralised and distributed) orchestration, choreography, and a novel composition mechanism called DX-MAN. We particularly focus on the fundamental semantics of these mechanisms instead of addressing specific implementation technologies. This is because semantics constitutes general theory that defines how to compose services conceptually rather than a concrete implementation (that can only be evaluated in specific scenarios). Significantly, fundamental semantics underlies so-called composition algorithms [8, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101, 102], programming frameworks [84, 103, 104, 105, 106, 107, 108], languages [109, 110] and platforms [111, 112, 113, 114, 115, 116, 117], which have been somehow confusingly included in existing “IoT service composition” surveys [3, 5, 24, 118, 119].

It is also essential to mention that IoT service composition is just another name for traditional SOA composition and it is done regardless of so-called service “architectures” such as the ones defined for Microservices. Microservice Architecture [120, 121, 122] has gained considerable attention in the last few years and is becoming increasingly important and popular for the development of IoT systems [123, 124, 125, 126, 127]. Every Microservice Architecture is an SOA, but not the other way round [128]. Hence, the service composition mechanisms presented in this sub-section can be used interchangeably in both Microservices and traditional SOA services. In fact, there are no composition mechanisms specifically aimed for Microservices.

Dataflows, or Flow-Based Programming [129, 130, 131], is a composition mechanism that defines implicit workflows as directed graphs where vertices receive input data streams, carry out some computation and pass the result to other vertices via an edge for further processing [71, 132]. A centralised approach [83, 116] fully coordinates the exchange of data streams exogenously (i.e., from outside services), whereas a distributed one [37, 38, 133, 134] partitions a complex workflow dataflow over multiple coordinators. Currently, dataflows is the most popular IoT service composition mechanism, so there are plenty of available technologies for defining data-driven IoT workflows [83, 126, 135].

Orchestration defines explicit workflow control flow structures to coordinate the invocation of service operations exogenously and, like dataflows, it can be centralised or distributed. A centralised orchestration [72, 136, 137, 138] has full control over all the services composed, whereas a distributed approach (also known as “decentralised orchestration” [139, 140, 141, 142, 143, 144, 145, 146, 147, 148]) defines workflows that characterise a collaborative exchange of workflow control flow over the network. Although orchestration is not as popular as dataflows, there are some implementations available for this mechanism to support the definition of control-driven IoT workflows [149, 150, 151].

Choreography [136, 137, 138, 152, 153] is another composition mechanism that defines workflow control flows for the invocation of operations in services. Unlike orchestration, it relies on a public protocol which specifies a global “service conversation” via decentralised interactions, and it is modelled using a choreography modelling language [122, 138, 153]. When a choreography is enacted, the composed services exchange control according to the protocol to realise decentralised workflows. It is because of this decentralised nature that there is an increasing trend of implementing technologies for choreographing IoT services [154, 155, 156]. Notably, some of these technologies (e.g., [155]) implement choreographies based on the data-driven paradigm with no notion of public protocols, which do not define any composite service but a bunch of interactions via events or decentralised message passing. So, they do not follow the standard definition as noted by [35].

DX-MAN [157, 158, 159] is a model that uses exogenous composition operators [160, 161] to algebraically compose IoT services in a hierarchical bottom-up manner. The result of composition is not a workflow, but an IoT composite service which is semantically equivalent to a potentially infinite family of (explicit) workflow control flows. As DX-MAN takes the best properties from choreography and orchestration, it enables decentralised data exchanges over the network while decoupling services via (exogenous) workflow control flows [162]. Currently, there is only one platform available to support the definition of algebraic IoT systems [163].

To continue the discussion, Section 6 describes the above composition mechanisms in detail and presents a concrete analysis in terms of functional scalability requirements.

4. A Large-Scale IoT Scenario: Smart Parking System (SPark)

To illustrate the context for scalability requirements, this section presents a large-scale IoT scenario in the smart parking domain. The scenario tackles a common problem of large cities and is described as follows.

With the increase of population, large cities have had to deal with daily traffic congestion caused by drivers actively searching for parking spaces, especially during rush hours. As a consequence, there are increased carbon emissions as well as waste of commuters’ time and money [164, 165]. This section presents a large-scale smart parking system, SPark, for self-driving vehicles which efficiently find (and reserve) the nearest parking space in a smart city. SPark thus helps to improve parking space utilisation, shorten parking search time, reduce environmental pollution, minimise parking costs and fuel consumption, and alleviate traffic congestion [164].

SPark operates in a smart city with plenty of parking spaces equipped with occupancy sensors whose data is managed by Infostations. Although it is an urban infrastructure device able to collect up-to-date occupancy status from all sensors in range, an infostation only pulls data from the sensors near a vehicle. Figure 4 illustrates SPark with four self-driving cars, where a vehicle gets its location and requests a parking space from the nearest Infostation. The Infostation then pulls data from the nearby sensors to determine the near-
est parking space that is free. To avoid two different vehicles chasing the same parking space, the space is reserved and paid for in advance. Finally, the vehicle displays the desired route and drives towards the selected parking space. Figure 5 depicts the general workflow of SPark.

Figure 4: A smart city with SPark.

Figure 5: SPark workflow.

To achieve its goal, SPark composes a huge amount of IoT services distributed across a city. It is then an ultra large-scale system [23, 24, 25, 26] because sub-systems (i.e., services) may potentially integrate other sub-systems (i.e., services) and so on. Figure 6 depicts the relationship between services and sub-services in SPark. We distinguish between atomic services and composite services. An atomic service is the most primitive unit with no internal structure, whilst composite services integrate sub-services and can be integrated into even more complex composites.

To hide complexity and protect behaviour integrity, we assume that the composite services of our example are encapsulated. As IoT composite services potentially reside on different business domains [166], SPark cannot be “decomposed” using a top-down approach, but it should be composed in a bottom-up fashion by reusing existing compositions [27, 31]. Figure 6 shows the resulting hierarchical service relationship.

Note that ellipses indicate that services may provide multiple operations or compose many other services. Also note that, in practice, atomic services can be defined as composite services. For example, DrivingCtr could be a complex service that integrates services for planning a path and controlling a vehicle. As another example, the Display service may internally use a web mapping service and a visualisation service for displaying a route. An alternative (larger) view of SPark can be found in Appendix A. For clarity, this section only shows a simplified version of SPark which is incrementally described below.

The SensorNetwork composite is a wireless network that composes a group of dedicated atomic Sensor services. It provides the SensorNetwork.pullStates operation as an interface for collecting parking space status in parallel. The collection is done by invoking the Sensor.pullState operations from the sensors near the vehicle.

The CityManagement composite service composes multiple SensorNetwork composites and one atomic Booking service. It provides the CityManagement.getParking operation for finding and reserving the best (i.e., the free and nearest) parking space. To do so, it collects sensor states with the SensorNetwork.pullStates operation, and then determines which parking spaces are free. Finally, it reserves the nearest free parking space using the Booking.book operations.

The Payment composite is an online electronic payment service that composes two payment providers: Provider1 and Provider2. It chooses which payment method to use when the operation Payment.pay is invoked. On the one hand, Provider1 is an atomic service with the operations payVisa and payMaster (for paying with Visa or Mastercard). On the other hand, Provider2 is an atomic service with the operation payWallet (for paying with an eWallet).

The Vehicle composite encompasses two different behaviours, and composes the atomic services GPS, Display and DrivingCtr. The Vehicle.getCurrentLocation operation is an interface for the behaviour of GPS.getLocation, which gets geospatial positioning information. The Vehicle.driveVehicle operation is more complex, as it invokes Display.showMap so as to plan, compute and visualise the route on the vehicle’s display. Then, it executes DrivingCtr.drive to autonomously drive the vehicle towards the desired parking space.
**SPark** is the most complex composite service, since it composes the services *CityManagement*, *Payment* and *Vehicle*, and provides the *SPark.findBestParking* operation for the encapsulation of the whole system's behaviour. The behaviour is a workflow for the sequential invocation of *Vehicle.getCurrentLocation*, *CityManagement.getParking*, *Payment.pay* and *Vehicle.driveVehicle*. Appendix B describes the complete workflow of our scenario.

As the *SPark* workflow spans multiple administrative domains, our motivating example requires the distribution of services across different geographical locations. Table 1 shows a possible physical deployment configuration. In particular, *CityCouncilCloud* is a virtual thing where services *CityManagement*, *Payment* and *Booking* are deployed. *ParkingSpace* is a physical thing whose occupancy status is provided by the *Sensor* service. *Infostation* is a physical thing that collects data from sensors within a wireless range, via the *SensorNetwork* service. *ProviderServer1* and *ProviderServer2* are physical things of different payment provider companies, where services *Provider1* and *Provider2* are deployed. *Vehicle* is a physical thing that moves around the city, searching for a parking space, which provides the services *SPark*, *Vehicle*, *GPS*, *Display* and *DrivingCtr*. Note that deploying a composite service (e.g., *SPark*) does not necessarily mean that the composed services should be deployed on the same thing. This is because IoT services operate on different administrative domains.

## 5. Functional Scalability Requirements

This section presents the functional scalability requirements of IoT systems in terms of *SPark*. These requirements were derived from an extensive review of the literature on large-scale IoT systems and serve as the foundation of our evaluation framework. The requirements are: (i) explicit control flow [29, 30]; (ii) distributed workflows [23, 31, 32]; (iii) location transparency [20, 33]; (iv) decentralised data flows [23, 32, 34]; (v) separation of control, data and computation [35, 36, 37, 38]; and (vi) workflow variability [23, 39, 40, 41].

### 5.1. Explicit Control Flow

Control flow defines the execution order of composed services [71], according to sequencing, branching or parallelising constructs [75]. It is explicit when there is a visible construct defining control flow in a service composition, whilst it is implicit when it needs to be inferred from the collaborative interaction of the composed services [71, 74, 138]. Figure 7 describes the difference between such concepts. The left side depicts visible constructs for the sequential execution of *A.opA1* and *B.opB1*. Contrastingly, the right side does not show any control flow constructs, as the workflow logic is hardcoded in the computation of the composed services.

![Diagram of explicit and implicit control flow](image)

**Figure 7:** Explicit control flow vs implicit control flow.

The number of composed services may become overwhelmingly large because of both the huge number of things involved and the complexity of workflow control flow. Consequently, execution failures become unavoidable, more challenging to manage and may potentially unleash catastrophic consequences (for individuals or societies) [167]. For that reason, explicit control flow becomes crucial to tackle functional scalability, since it facilitates monitoring, tracking, verification, maintenance and evolution of large-scale IoT composite services [29, 30, 122, 168, 169]. For instance, we can leverage explicit control flow to detect abnormalities in a *SPark* execution [170, 171, 172], or we could easily obfuscate workflow control flow in order to avoid malicious reverse-engineering [173, 174].

Imagine that *SPark* suddenly stops working because of a bottleneck in some service, so developers want to analyse the system execution flow to find out where the problem is. For this, they can leverage explicit control flow to display a visual representation of the execution paths that *SPark* has taken [29, 74, 175, 176]. By looking at the blueprint, developers can identify the services that perform poorly and react accordingly.

Implicit control flow has historically been a barrier for functional scalability since it hinders control flow visualisation, especially when the number of services increases [29, 30, 121, 122, 177, 178]. Although there are attempts to visualise control flow [178, 179, 180, 181, 182], transforming implicit control flow into an explicit one is still a challenging task, especially when the system workflow is complex. This issue has made software development companies stop composing services with implicit control flow. Netflix [183] is the most prominent case, which has particularly expressed its concern for monitoring composite service executions when control flow is implicit. To tackle this, it has recently developed Conductor [29] to move from compositions with implicit control to compositions with explicit control.  

---

3For example, control flow is explicit in imperative languages and implicit in declarative ones.
5.2. Location Transparency

Large-scale IoT systems are inherently dynamic and uncertain due to the presence of churn in the operating environment [20, 25, 27, 33, 184, 185, 186]. Churn means that things (and their services) dynamically connect and disconnect from the network as a result of auto-scaling, software upgrades, failures, poor connection and mobility. It is particularly evident when an IoT system uses resource-constrained things with a poor connection [187], or when there are mobile things involved [185, 188]. Hence, churn results in physical service locations (i.e., IP addresses) changing over time frequently. For example, the Spark’s Sensor service is a resource-constrained thing with limited connectivity, which is likely to experience network disconnections. Similarly, the service Vehicle may change its IP address because of its high mobility. The same happens to Provider1, Provider2 and Booking as they are deployed on the Cloud.

To deal with churn, IoT systems require location transparency, in order to ensure that atomic services are unaware of the physical location of other services [74]. Figure 8 illustrates this concept. In particular, the lower section shows that the (non-static) IP address of B.opB1 is hardcoded in A.opA1. The upper section shows a scenario where there is support for location transparency.

![Location Transparency](image)

**Figure 8: Location Transparency.**

Location transparency is typically achieved with a service discovery mechanism that dynamically queries a central service registry [52]. In client-side discovery, service providers register at startup in a registry which is later queried by service consumers. In server-side discovery, a router (e.g., a service bus like a gateway [112]) queries the registry and forwards requests to an available service provider on behalf of service consumers.

A service composition with no location transparency requires service consumers to know the location of service providers in advance. For example, without any support for location transparency, SPark would have to be updated every time a Vehicle changes location. Nonetheless, this is worrying because there is a massive number of vehicles constantly moving around a city and, therefore, changing location. Addressing this issue with a service discovery mechanism entails the addition of “intrusive” elements to the composition (e.g., a service registry or a naming service) which are not part of the semantics of a composition mechanism. In fact, an atomic service computation would be tightly coupled with the “intrusive” element, since the former needs to be updated whenever the location of the latter changes. We shall keep this in mind in Section 6.

5.3. Distributed Workflows

IoT service composition can define a centralised or a distributed workflow. It is centralised when a single entity governs the entire workflow control flow. Contrastingly, it is distributed when multiple entities collaboratively define control flow [74]. Figure 9 illustrates the contrast between a centralised and a distributed workflow. The upper part shows a central composite service that defines a workflow for the sequential invocation of A.opA1, A.opB1, A.opC1, A.opD1 and A.opE1. The lower part shows a possible distribution of the same workflow control flow over three composite services deployed on different things.

![Distributed Workflows](image)

**Figure 9: Centralised workflow vs distributed workflow.**

Although a centralised workflow facilitates the design and maintenance of an IoT system, implementing a large-scale IoT system using such an approach is inefficient and infeasible [133]. This is because a central entity constitutes a single point of failure and attack, and leads to a performance bottleneck since all control and data goes through it [27, 34, 140, 142, 144, 148, 189, 190, 191]. Moreover, a central entity negatively impacts the availability of an IoT system.

The distributed nature of IoT requires control and data to pass through geographically dispersed entities (potentially deployed on different business domains) [32, 37, 133, 166]. For that reason, no single domain should govern the entire composition workflow, since multiple domains (perhaps in the order of millions) may want control over their own workflow part [74, 190, 192]. For instance, the CityManagement composite may potentially be controlled by the City Council, and a payment provider company could operate the Payment composite. This issue clearly implies that every administrative domain should be able to manage their own workflow definition. Thus, a distributed workflow should be part of any IoT service composition mechanism, since it allows interoperability between different domains and improves load balancing, throughput and availability of an IoT system [74, 87].
5.4. Decentralised Data Flows

Data flow defines the way data elements are moved from one service to another in a service composition [71]. This process can be done in three different ways: centralised, distributed or decentralised.

In the centralised approach [112, 136, 193, 194], a single composite mediates the exchange of data between services (see Figure 10(a)). Although it facilitates data management, the mediator becomes a potential bottleneck and introduces additional network hops for data exchange, since all data passes through it. This negatively impacts QoS by increasing the response time, and leads to network congestion [34, 141, 142, 190, 195], especially when there are plenty of IoT services exchanging huge amounts of data continuously [24, 25, 187, 190, 196].

To avoid a single bottleneck, the distributed approach [133, 139, 140, 141, 142, 143, 144, 146] removes the central composite and distributes the load of data over multiple composites (see Figure 10(b)). Although this improves load balancing, it introduces unnecessary network overhead as data passes through many mediators, even if data is unimportant for them, i.e., the more mediators, the more network overhead.

IoT services must exchange data as efficiently as possible (by minimising network hops), in order to avoid performance bottlenecks, achieve better response time and improve throughput [147]. A decentralised approach provides the most suitable data exchange for service composition since it requires only one network hop to pass data directly from a service producer to a service consumer (see Figure 10(c)) [34, 117, 152, 162, 195, 197, 198, 199]. For example, the data generated by Booking.book should be passed to Display.showMap, without passing through any other entity that does not require the produced data (e.g., the CityManagement composite or the Vehicle composite). In general, the amount of data transmitted in SPark may potentially be huge due to the large number of services involved of which sensors generate data continuously. Therefore, SPark requires a composition mechanism with support for decentralised data flows to provide an optimal QoS.

5.5. Separation of Control, Data and Computation

Large-scale IoT systems may potentially span multiple administrative domains and exhibit a high degree of heterogeneity in many different forms [25, 74, 200]. For instance, there may be different service providers (e.g., Amazon AWS IoT and IBM Watson), a wide variety of programming languages (e.g., Swift and embedded C), multiple operating systems (e.g., Contiki and TinyOS) and different network communication protocols (e.g., CoAP and MQTT). For that reason, service composition mechanisms must provide the means to deal with such heterogeneity, in order to compose large-scale cross-domain IoT systems. This is, in fact, one of the major challenges for building IoT systems [200].

To enable flexible service composition in such heterogeneous environments, control flow, data flow and computation should be orthogonal [35, 36, 38, 76, 144, 201, 202]. This would enable separate reasoning of concerns so system developers can focus on IoT service composition, while service developers focus on efficient service functionality [37, 74, 76]. Consequently, services are workflow agnostic because workflow control flow is never embedded in the computation of many services. Moreover, the separation of control and computation facilitates workflow monitoring [29].

Figure 11 illustrates a separation of control, data and computation. There are two computations defined in A.opA1 and B.opB1. The control flow part defines a workflow for the sequential invocation of A.opA1 and B.opB1, without considering data flow and computation. The data flow part defines intermediate processing of the output from A.opA1, before sending it to the input of B.opB1. When control is mixed with data, such processing represents an extra control flow step which is intrusive to the original workflow.

The separation of data flow will additionally enable separate data management for improving performance without considering control flow [35, 162]. Similarly, control flow can be used in isolation for defining efficient deployment strategies that do not consider data flow. Moreover, different technologies can be used for implementing control flow, data flow and computation separately [35]. For instance, developers of SPark could use CoAP for passing control between services, the Blockchain for managing data flows and embedded C for implementing service computation. Providing independent reasoning of concerns also enables a separate validation and verification (V & V) of services.

When control is mixed with computation, a service
provider and a service consumer are tightly coupled because invocations are originated in the consumer’s computation. Thus, changing workflow control flow in one service requires further changes in the respective computation. This rigidity evidently limits the scalability of IoT systems because it is difficult to add, remove, change and replace services (and system workflow control flow). For that reason, reusing services is not possible at scale when control is mixed with computation [29, 37, 71, 74, 203].

Suppose there is a branching control flow structure in the computation of Booking.book, for invoking either Provider1.payVisa or Provider2.payWallet. As a result, Booking.book is not reusable as it is since it must be adapted to the requirements of other systems, e.g., it must be updated when two new payment providers come into play (e.g., Provider3 and Provider4). As another example, SPark could need the parallel execution of Payment.Pay and Vehicle.driveVehicle, in order to improve concurrency. In this case, the sequence of invocations hardcoded in SPark.findBestParking must be replaced with a parallel control flow structure.

Generally speaking, large-scale IoT systems require separate reasoning of control, data and computation for independent maintenance, validation, verification, reuse and evolution of those concerns. This separation of concerns could also result in reduced time to market and reduced software production and maintenance costs [74].

5.6. Workflow Variability

Large-scale IoT systems operate in highly dynamic environments subjected to variability caused by external or internal factors [39, 41, 204, 205]. External factors are beyond the scope of the system and include changes in requirements and increasing workloads. Internal factors are associated with the system operation and include system failures and sub-optimal behaviours.

A service composition mechanism must support the definition of alternative behaviours, in order to adapt a composite to changes in both the external and the internal environment. As manually choosing alternative behaviours is a costly and inefficient management process, when there are many services in the composite, behaviours must be selected autonomously (i.e., with no human intervention) [206]. Thus, variability of behaviour is a crucial desideratum for the realisation of large-scale autonomous IoT systems [23, 39, 40, 41, 87, 207].

Workflow variability [157, 208] allows the definition of alternative control flow constructs (i.e., behaviours) in a service composition (see Figure 12), and it is particularly useful for autonomously changing workflows at runtime. For instance, the SensorNetwork composite may define variable parallel behaviours for pulling data, depending on a vehicle’s location. For one vehicle, it may pull data from Sensor1 and Sensor2, whilst for another one it could pull data from Sensor10, Sensor29 and Sensor34. As another example, consider multiple payment service providers that offer different QoS (which is always fluctuating according to different workloads). For this, a variable branching construct can be used to dynamically choose the Provider service with the best QoS.

![Figure 12: Workflow variability.](image)

When there is a family of related compositions, a Greatest Common Denominator [208] is a base variability model that can be reused for defining alternative compositions (also known as configurations). For example, suppose a SPark vehicle can be either manual or self-driving. A manual vehicle requires the services GPS and Display, whilst a self-driving one uses the service DrivingCtr in addition. For this, the Vehicle composite of Figure 6 would be the Greatest Common Denominator, which can be reused for defining two alternative behaviours for two different vehicles.

Workflow variability is not only useful to accommodate the requirements of different vehicles, but also meaningful for different cities and users. Consider the case of Northern Ireland where many cities offer free on-street parking, and a few others (e.g., Belfast, Lisburn and Newry) impose a tariff [209]. Here, some SPark workflow variants may require a Payment composite, while others not. At the city scale, it would become very difficult to define workflows from scratch since many services would need to be changed and customised. Users can also require different workflows according to their needs, e.g., one user may require pre-payment, whereas another one may require post-payment. However, manually changing behaviour at runtime to accommodate different user requirements is infeasible. Thus, workflow variability represents a suitable solution for tackling the above scenarios.

In order to define workflow variability, a service composition mechanism must enable total compositionality by which all behaviours (e.g., operations) from the composed services are semantically available in a composite service [157, 159]. This concept contrasts with partial compositionality where only named and selected behaviours are semantically preserved, leading to a combinatorial explosion of behaviours as the number of services increases [159].

![Figure 13: Dichotomy between total and partial compositionality.](image)

For example, there are $2^k - 1$ possible scenarios for pulling sensor data, where $k$ is the number of sensors.
and $A.\text{op}_A$, or an alternative sequence for the execution of $A.\text{op}_A$, $B.\text{op}_B$ and $A.\text{op}_A$. These behaviours are impossible to achieve with partial compositionality which allows the definition of only one fixed workflow at a time.

To answer $RQ6$, we need to determine the compositionality of a mechanism which can be either total or partial (see Section 5.6). To do so, we investigate the following research questions:

- **RQ7**: What is the resulting type from composition?
- **RQ8**: How many workflows does the composition mechanism define?

### 6.1. Dataflows

Dataflows, or Flow-Based Programming [129, 130, 131], is a composition mechanism that defines a workflow using data transformations (e.g., filter, split, union and sort) as well as exogenous data exchange between services [71, 132]. A dataflow description is a directed graph where vertices are asynchronous data processing units (invoking service operations), and edges are connections for passing data streams between vertices via the network (by message passing or events). A vertex explicitly defines input ports and output ports. When it receives data from all inputs, it performs some computation and writes results in output ports. The resulting data is then moved to other vertices via an edge. This process is illustrated in Figure 14.

![Figure 14: Composition by dataflows.](image)

Dataflows can be centralised or distributed. A centralised dataflow [83, 116] defines a single coordinator for managing an entire graph and exogenously invokes service operations. A distributed dataflow [37, 38, 133, 134] partitions and distributes a complex graph over multiple coordinators that interact directly by exchanging data between vertices.
is shown in Figure 14(b), where there is an edge between V-B1 and V-C1 for moving data from the Flow1 composite to the Flow2 composite.

Dataflows are increasingly popular for composing IoT systems. In particular, they are widely used for the Internet of Data (IoD) [210] which involves data collection from multiple sources (e.g., sensors), data analysis and control of the physical world. This paradigm has been referred to as Sense-Compute-Control (SCC) [211]. Currently, there are many platforms for composing IoT services using dataflows. Examples include Node-RED [83], COMPOSE [214], Glue.Things [116], LabVIEW [135], Paraimpu [215], Virtual Sensors [111], SpaceBrew [216], FogFlow [18], ASU VIPLE [217], ThingNet [126], Calvin [218], IoT Services Orchestration Layer [219], NoFlo [220] and many others [221, 222, 223, 224].

As the Web 2.0 became more data-centric and user-friendly [65, 71], dataflows have gained popularity for IoT through mashups. Mashups [225] are realised by dataflows [71, 226], and they allow the composition and visualisation of data streams on a graphical user interface displayed on the Web [65, 71, 227]. Examples of mashup tools include WoTKit [228], IoTMaas [196] and Clickscript [56].

Dataflows have been accepted as coordination languages since a graph is defined in a coordinator that exogenously invokes services according to a dataflow description [129, 130, 133]. A dataflow graph is typically created with a graphical editor and executed by an engine (i.e., the coordinator), and it is triggered by either timing constraints or events.

A dataflow coordinator is the only entity aware of service locations, and provides separation between data and computation. This separation allows service developers to focus on data stream computation while system developers wire up vertices exogenously [133]. However, despite the aforementioned advantages, decentralised data flows are not supported as data streams always pass through data flow coordinators.

Although passing data between vertices is explicitly defined in a dataflow graph, control flow is implicit in the collaborative data stream exchange. This is because control flow statements are not visible in the graph specification.

In general, a graph specification is a single flat workflow of named and selected service operations. It might seem that a distributed dataflow provides multiple workflows. However, this is not true because a distributed dataflow graph is just a single nested workflow, distributed over different coordinators. Thus, dataflows only provide partial compositionality and do not support workflow variability (see Table 2).

Table 3 summarises the results of our analysis of data flows w.r.t. the scalability desiderata. Both centralised dataflows and distributed dataflows have similar characteristics. The only difference is that the latter provides support for distributed workflows by partitioning a dataflow graph over multiple coordinators.

### 6.2. Orchestration

Orchestration can be centralised or distributed. Centralised orchestration [72, 136, 137, 138] describes interactions between services from the perspective of a central coordinator (also known as orchestrator) which has control over all parties involved. It explicitly defines workflow control flow to coordinate the invocation of service operations, in order to realise some complex function that cannot be achieved by any individual service [69, 70, 229]. In a distributed orchestration, also known as "decentralised orchestration" [139, 140, 141, 142, 143, 144, 145, 146, 147, 148], multiple coordinators collaboratively define workflow control flow.

An orchestration is typically defined using a workflow language such as BPEL [70, 81, 230, 231, 232, 233, 234, 235] or BPMN [86, 236]. The resulting workflow has tasks for passing control among services according to explicit control flow constructs (for sequencing, parallelising, branching and

looping) [71]. In distributed orchestration, the interaction between coordinators can be done in three different ways: (i) with an extra task [140], (ii) with two extra tasks [141, 142, 148] or (iii) without any extra task [139, 144, 145]. In (i), an orchestration invokes the interface of another one using an external task to the system’s workflow control flow. In (ii), there are two different tasks for receiving and passing control (and data) between two orchestrations. Finally, in (iii), two orchestrations interact by moving control (and data) directly between the tasks of the system’s workflow control flow.

An orchestration engine is responsible for executing a workflow process by invoking service operations in a given order. Although traditional engines can be used (e.g., Camunda BPM workflow engine [86, 237], Activiti [238, 239] and AWS Step Functions [151]), recently we have seen the emergence of orchestration engines particularly designed for IoT systems (e.g., PROtEUS [149] and [150]).

Figure 15(a) illustrates a centralised orchestration for the services A, B, C and D, where the coordinator Orch1 defines a “composite service” for the sequential invocation of A.opA1, B.opB1, C.opC1 and D.opD1. Three distributed versions are depicted in Figure 15(b). In the former, Orch1 defines a “composite service” for the sequential execution of A.opA1 and B.opB1, and then uses an extra task to pass control (and data) to Orch2. Orch2 defines another “composite service” to sequentially invoke C.opC1 and D.opD1. The second distributed version uses two extra tasks for passing and receiving control (and data) between Orch1 and Orch2. Finally, in the last distributed version, control and data are passed directly from B.opB1 to C.opC1.

A glance at Figure 15 reveals that services are workflow agnostic because an orchestrator is the only entity aware of the location of other services. Having workflow agnostic services implies that an orchestrator provides separation between control flow and computation. This separation allows service developers to focus on efficient service functionality (i.e., computation) while system developers focus on workflow control flow in orchestrator(s).

Although a central coordinator facilitates the management of control flow logic, it easily becomes a performance...
bottleneck because all data passes through it [140, 142]. This is because data follows control [71, 162]. Furthermore, the resulting composite service is a single flat workflow, for the invocation of named and selected operations, which must be transformed into a service [159, 240]. For that reason, orchestration only provides partial compositionality and does not support workflow variability (see Table 4).

Table 5 summarises the results of our analysis of orchestration w.r.t. the scalability desiderata, where we can see that centralised orchestration and distributed orchestration have similar characteristics. The only difference is that the latter supports distributed workflows via the partition of workflow control flow over multiple coordinators.

6.3. Choreography

A choreography describes service interactions from a global perspective using a public contract (also known as protocol) [136, 137, 138, 152, 153]. The contract specifies a “conversation” among participants via decentralised message exchanges, which can be modelled by a global observer using a choreography modelling language [122, 138, 153]. An interaction-based model allows the definition of event-driven or request-response messages by connecting required and provided interfaces. Examples include WS-CDL [241] and Let’s Dance [242]. An interconnected interface model, on the other hand, allows the specification of control flow per participant. Examples include BPEL4Chor [240], Web Service Choreography Interface (WSCI) [243] and BPMN [244].

A protocol defines roles for the collaborative realisation of a global workflow with no control over the internal details of the participants involved [229]. A role explicitly describes a participant workflow control flow in terms of expected and produced messages. When a concrete service instance plays a role, it must behave accordingly by exchanging messages with other instances, using either direct message passing (e.g., invoking REST APIs) or events [63, 74, 117, 122]. This process is known as choreography enactment.

IoT is moving towards a more decentralised environment to reduce the bottleneck caused by centralised environments. As choreographies represent a natural way of dealing with such decentralisation, there are currently some platforms for composing IoT services by choreographies, e.g., CHOReVOLUTION [154], ChorSystem [246], Actorsphere [156], BeC³ [117] and TraDE [35].

Figure 16 illustrates a sequential choreography for the services A, B, C and D, where a protocol (defined with standard BPMN 2.0 notation [236]) specifies that B.op_B1 expects a message from A.op_A1, C.op_C1 a message from B.op_B1 and D.op_D1 a message from C.op_C1. When the choreography is enacted, there is a chain reaction that starts with the invocation of A.op_A1 and finishes with the execution of D.op_D1.

Figure 16: Composition by choreography.

Figure 16 shows that workflow control flow is explicitly defined in the protocol. During enactment, control is passed alongside data in every invocation, so services need to be aware of the location of other services. Of course, a service registry can be used, but this entails adding an “intrusive” element external to the composition (see Section 5.2).

Like orchestration, the resulting composition is a flat workflow for the invocation of selected and named operations (specified in the protocol). If the resulting workflow needs to be further composed, a choreography needs to be transformed into a service [159, 240]. For that reason, a choreography is partially compositional and workflow variability is not supported (see Table 6). Table 7 summarises the results of our analysis of choreography w.r.t. the scalability desiderata.

6.4. DX-MAN

DX-MAN [157, 158, 159] is an algebraic model where IoT services and service composition operators are first-class semantic entities. A service is a stateless distributed unit of composition which can be either atomic or composite, and its semantics is a workflow space (i.e., a family of workflow variants). A composition operator defines variable control flows between families of workflow variants (see Figure 17(b)).

![Diagram of DX-MAN model](image)

Figure 17: DX-MAN model.

An atomic service is formed by connecting an invocation connector with a computation unit (see Figure 17(a)). It is a finite workflow space whose elements invoke a different operation implemented in the computation unit via an invocation connector. As a computation unit is semantically identical to a traditional SOA service (because it is a set of operations), DX-MAN atomic services and SOA atomic services are semantically different (cf. Section 2.1).

A composite service connects a composition operator with multiple (atomic or composite) sub-services (see Figure 17(c)), which is equivalent to connecting a composition operator with multiple sub-workflow spaces. The result is a composite workflow space whose workflow variants invoke elements of atomic sub-workflow spaces and/or entire composite sub-workflow spaces, according to the control flow definition of the composition operator being used. There are composition operators for sequencing (i.e., sequencer), branching (i.e., inclusive selector and exclusive selector) and parallelism (i.e., paralleliser). Figure 18 shows that the sequencer and paralleliser operators define infinite workflow variants, while the branching operators define $2^n - 1$ variants s.t. $n$ is the total number of atomic sub-service operations plus the number of composite sub-workflow spaces. For further details on this matter, see [157].

![Diagram of DX-MAN composition operators](image)

Figure 18: DX-MAN composition operators.

In addition to composition operators, DX-MAN provides special transformation operators (called adapters) for sequencing, branching, parallelising, looping and guarding over individual workflow spaces. Hence, DX-MAN is Turing complete [247]. Currently, there is only one platform that implements the DX-MAN model [163], and it is available at https://github.com/damianarellanes/dxman.

In DX-MAN, a composition is done incrementally in a bottom-up fashion. So, a hierarchical connection structure of operators sits on top of atomic services. Figure 19(a) shows a DX-MAN composition that involves four atomic services and three composite services. The first step is to model the atomic services $A$, $B$, $C$ and $D$ with the invocation connectors $I_A$, $I_B$, $I_C$ and $I_D$. This process results in the atomic workflow spaces $W_A$, $W_B$, $W_C$ and $W_D$, respectively. In the next hierarchy level, we create the composite services $E$ and $F$. To do so, we use the composition operator $SEQ_E$ to define a composite workflow space $W_E$ from the atomic sub-workflow spaces $W_A$ and $W_B$. Likewise, we define the composite workflow space $W_F$ using the operator $SEQ_F$ which operates on the atomic sub-workflow spaces $W_C$ and $W_D$. Finally, we create the top-level composite service $G$. For this, we use the composition operator $SEQ_G$ which defines the composite workflow space $W_G$ from $W_E$ and $W_F$.

![Diagram of DX-MAN composition](image)

Figure 19: Composition by DX-MAN.

Note that workflow spaces from sub-services are available.
in the next hierarchy level thanks to the algebraic semantics of the model. Consequently, the result of algebraic composition is not a single workflow, but a (potentially infinite) workflow space (i.e., a service) of workflow variants. Thus, DX-MAN supports total compositionality (see Table 8).

When a composition is done, an abstract workflow tree is automatically derived, which represents the hierarchical control flow structure of the composite (see Figure 19(b)). To select a particular variant, a concrete workflow tree must be created, which is just a projection function over a composite workflow space. See [157, 158] for further details.

Figure 19(b) shows the abstract workflow tree of our example from which we can choose infinite sequential workflow variants (see Figure 19(c)). One case is depicted in Figure 20, where a concrete workflow tree is created for the sequential execution of $A.@op_{A1}, B.@op_{B1}, C.@op_{C1}$ and $D.@op_{D1}$. Figure 21 shows another variant where a different concrete workflow tree is defined to invoke $A.@op_{A1}$ and $D.@op_{D1}$ sequentially.

Table 8: Compositionality of DX-MAN.

Table 9 summarises the results of our analysis of DX-MAN w.r.t. the scalability desiderata.

Note that a DX-MAN composition has composition operators for the coordination of workflow control flow only. This is because data flow and control flow are modelled separately for each workflow variant. The paper [162] describes further details on how to define data flows per variant.

A glance at Figures 20 and 21 reveals that data, control and computation are independent concerns. Thus, data is exchanged in a P2P fashion between atomic services, while composition operators coordinate workflow execution by passing control only. The coordination can be done in a distributed way since composition operators can be deployed on different things [159]. As coordination happens from outside services, computation units do not interact with one another, which results in independent distributed computations.

When an invocation connector receives control, it reads data from a decentralised data space (i.e., the Blockchain in the current implementation), invokes a service operation and writes results in the space. For that reason, only invocation connectors know the location of the connected computation units (i.e., service implementations). Furthermore, as invocation connectors perform operations on the data space, composition operators never exchange data during workflow execution. This (transparent) decentralised data exchange is achieved by the separation of control and data [162].

7. Evaluation

This section presents an evaluation of service composition mechanisms w.r.t. compositionality and the functional scalability requirements of IoT systems.

Table 10 summarises the analysis on compositionality presented in Section 6 to answer the research questions RQ7 and RQ8. It shows that DX-MAN is the only mechanism that enables total compositionality since algebraic composition yields a service with a potentially infinite number of workflow variants. The other mechanisms define only one workflow at a time as the composition result is not a service, but a single flat workflow that invokes selected and named operations.

Table 11 summarises our analysis of scalability desiderata and Table 12 shows the respective satisfaction degrees. Our interpretation of the results is presented below.

8. Discussion

This section discusses the results presented in Section 7 and covers additional issues concerning compositionality, scalability requirements and the relationship between them.

Our results show that explicit control flow is supported by the majority of the mechanisms. In particular, orchestration defines control flow in orchestrators, choreography in a protocol and DX-MAN in composition operators. Dataflows is the only one that does not support such a requirement.

Workflow distribution is also meet by the majority of the mechanisms, except centralised dataflows and centralised orchestration where a coordinator fully governs a workflow.

Almost all composition mechanisms use a coordinator to exogenously define workflow(s) and, therefore, ensuring the separation of at least two concerns. In particular, orchestration and DX-MAN separate control and computation, while dataflows orthogonalises data and computation. Such separation enables location transparency as only coordinators are aware of atomic service locations. Choreography is the only mechanism without any support for location transparency, since control and data are mixed with computation.

There is a special choreography implementation based on the data-driven paradigm in which some computation is triggered once input data becomes available [199]. As a protocol must explicitly define workflow control flow, the analysis presented in Section 6 is also applicable.

Generally speaking, avoiding coordinators allows choreography styles to support decentralised data flows. So, there is a trade-off between coordination and decentralised data flows. DX-MAN obviates this problem by separating data in addition to control and computation. This separation enables the realisation of decentralised data flows, without considering neither control nor computation. So, data never passes through composition operators (i.e., coordinators) [162].

Some orchestration approaches [34, 146, 195, 198] partially separate control from data algorithmically. To achieve this, coordinators pass data references alongside control, rather than exchanging data values. However, analysing data dependencies to extract references is a challenging task because data and control are still semantically entangled.

For orchestration and dataflows, a coordinator is commonly referred to as a composite service. However, it is just a composition of specific operations (i.e., a workflow) that must be transformed into a service, rather than a composition of entire services (with all their provided operations). Only DX-MAN achieves an actual composition of services (not operations) as it defines a composite service without any transformation step while preserving all service operations from which multiple workflow variants can be derived. Thus, algebraic composition equates to total compositionality which, in turn, implies workflow variability. A DX-MAN composite service is in fact semantically equivalent to a (potentially infinite) set of orchestrations. This is because each element in a composite workflow space is a different composition workflow as regarded by existing mechanisms. For any existing composition mechanism to be equivalent to a composite workflow space, it would require to include all possible combinations of execution paths in the workflow definition, leading to a combinatorial explosion problem. While it is true a configurable workflow [208] can deal with this issue, it does not define multiple workflows at a time but just a single workflow that can be manually configured.

In this paper, we analyse the fundamental semantics of current service composition mechanisms that allow the definition of IoT workflows. However, other mechanisms must be considered even if they do not allow the explicit definition of behaviour, e.g., port connections [248] and ensemble-based composition [249]. Moreover, we did not analyse service interactions where there is no definition of composite services such as direct message passing [250], broker-based interactions [112] and event-driven interactions [251]. For this, we
refer the reader to another paper [74].

Different composition mechanisms can coexist in the same system. For example, it is possible to build a system where some services are composed using orchestration while others are composed by choreography [155, 252]. Our intention is not to analyse the combination of different composition mechanisms, but to analyse them individually. Clearly, our analysis results apply to such a combination.

9. Conclusions

Functional scalability becomes a crucial concern for IoT systems as the number of available services increases. For that reason, we need to look back at the foundations of service composition in order to tackle this challenging problem. In this paper, we analysed the semantics of current IoT service composition mechanisms, using an evaluation framework that considers six functional scalability requirements: (i) explicit control flow; (ii) distributed workflows; (iii) location transparency; (iv) decentralised data flows; (v) separation of control, data and computation; and (vi) workflow variability. Our results suggest that DX-MAN is the composition mechanism that best fulfils the functional scalability requirements of IoT systems. This is not surprising since such a model was designed with scalability desiderata in mind.

It is important to note that, except DX-MAN, there are no new composition mechanisms developed in the last decade. This crisis is a worrying situation that must be prioritised and remedied because of the inherent scale that IoT systems pose. Only DX-MAN was designed with this in mind, but we expect further developments on this in the coming years.

We do not claim that the scalability requirements we analyse here are complete, as other characteristics must also be considered. Nevertheless, we believe our evaluation framework has included the most critical ones and provides a useful starting point for further extensions that consider other functional scalability desiderata such as dynamic reconfiguration, the number of messages exchanged and the support for implicit/explicit data flows. The framework can thus be refined by other researchers when conducting further studies on IoT service composition mechanisms.

Appendix A

A larger view of SPark is shown in Figure A.1, where there are new composite services representing Private Parkings of a smart city. Also, the Display service has been converted into a composite that uses the atomic services WebMap and Visual. There is also a new composite service called PathPlanning that composes multiple TrafficMonitor composites and multiple atomic People services. In particular, a TrafficMonitor composite has multiple atomic services that represent congestion sensors and cameras (distributed across a city). Furthermore, the Vehicle composite has been endowed with multiple atomic ChargSt services (for charging the battery of a self-driving vehicle). Finally, the DrivingCtr service has been converted into a composite service with the atomic services Brake and Steering.

It is important to note that the larger view shown in Figure A.1 can be expanded into an even larger composition which may become infeasible to depict in a single document.
Evaluating IoT Service Composition Mechanisms for the Scalability of IoT Systems

Figure B.1: SPark workflow control flow.

Appendix B

Figure B.1 illustrates the complete workflow of SPark which starts with the on-demand execution of SPark.findBestParking. Next, the SPark composite gets the current vehicle’s location by invoking the operation Vehicle.getCurrentLocation which, in turn, invokes GPS.getLocation. Then, it invokes the CityManagement.getParking operation which internally executes the SensorNetwork.pullStates operation from the nearest InfoStation. In particular, SensorNetwork.pullStates pulls the states (in parallel) from the sensors close to the vehicle’s location, using the respective Sensor.pullState operations. Next, the CityManagement.getParking operation uses the sensor states to determine the best (i.e., the free and nearest) parking space and then reserves that parking space using Booking.book. Then, control is passed to the Payment.pay operation which decides to invoke Provider1.payVisa, Provider1.payMastercard or Provider2.payWallet. Finally, the Vehicle.driveVehicle is invoked for implicitly calling Display.showMap and DrivingCtr.drive, in that order.
