ABSTRACT OF THESIS submitted by Karthigeyan Ramesh Kumar

for the Degree of Master of Science by Research and entitled

A Study of Element Abundances of Evolved Stars in the Galactic Globular Cluster M5. 2015.

I present the iron abundance and abundance ratios for 9 elements: Si I, Ca I, Ti I and Ti II, Cr I, Y II, Ce II, Nd II and Er II with respect to Fe in a sample of 55 stars along the RGB and AGB of the globular cluster M5. The spectra were obtained using the Hectochelle spectrograph at the Multiple Mirror Telescope. The spectral coverage was from 5070 Å to 5390 Å, 6010 Å to 6510 Å and 6391 Å to 6873 Å.

An average iron abundance [Fe/H]$=-1.29\pm0.15$ dex was found, consistent with Harris (2010). The cluster averages of [Si/Fe], [Ca/Fe], [Ti I/Fe], [Ti II/Fe], [Cr/Fe], [Ce/Fe], [Nd/Fe] and [Er/Fe] are 0.16 ± 0.17, 0.13 ± 0.12, 0.4 ± 0.15, 0.31 ± 0.13, 0.10 ± 0.41, 0.01 ± 0.16, 0.13 ± 0.13, 0.52 ± 0.14, 1.27 ± 0.18 dex, respectively. The [Ti II/Fe] matches the literature value. The [Si I/Fe] and [Ca/Fe] are found to be lower than the reported values while the other elements of this study show a higher abundance. An anti-correlation is found between the abundance ratios and the iron abundance which can be explained due to an artificially high spread in [Fe/H]. The combined behaviour of α-elements is also studied and we report an enhancement of α-elements relative to iron seen in this cluster. The abundance variations do not show any trend with the distance from the cluster centre. The obtained spectroscopic temperatures are found to match the photometric temperatures within the error margins except for three stars. An attempt is made to differentiate the RGB and AGB stars using their derived masses. The systematic offset in $\Delta\mathrm{T}_{eff}$ between RGB and AGB prevents us from accurately calculating the mass loss in the RGB.

Declaration

I declare that no portion of the work referred to in the thesis has been submitted in support of an application for another degree or qualification of this or any other university or other institute of learning.

List of Abbreviations and Symbols

The following abbreviations and symbols are used throughout this thesis:

1D − One Dimensional

AGB − Asymptotic Giant Branch

CMD − Colour–Magnitude Diagram

CNO − Carbon-Nitrogen-Oxygen

CWL − Centre Wavelength

E.P. − Excitation Potential

EW − Equivalent Width

FWHM − Full Width at Half Maximum

HRD − Hertzsprung-Russell diagram

HB − Horizontal Branch

ISM − Interstellar Medium

$L_\odot$ − Solar Luminosity

LMC − Large Magellanic CLoud

LTE − Local Thermodynamic Equilibrium

$M_\odot$ − Solar Mass

MSTO − Main Sequence Turn Off

MMT − Multiple Mirror Telescope

RGB − Red Giant Branch

rms − root mean square

SAO − Smithsonian Astrophysical Observatory

Introduction

1.1 Motivation

Recent studies of globular clusters suggest that they contain multiple generations of star formation, e.g. D'Ercole et al. (2008), Carretta et al. (2009b), Dalessandro et al. (2014), etc. Here, I will study the chemical composition of evolved stars in the globular cluster M5. This knowledge could then help us understand the cluster's formation and the chemical enrichment of the galaxy. We are also interested in testing whether there are any chemical differences between stars on the red giant branch (RGB) and stars on the asymptotic giant branch (AGB) on the Hertzsprung-Russell diagram (HRD).

Recent conflicting reports argue about the evolution of the second generation of stars. Campbell et al. (2013) observed the absence of second-generation AGB stars in NGC 6752 while Johnson et al. (2015) observed their presence in 47 Tuc. M5, having a metallicity between these two clusters and a well separated RGB and AGB, is ideal for testing stellar evolutionary models.

1.2 Globular Clusters

1.2.1 Historical Significance

Globular clusters were some of the first objects to be observed with the telescope. The first globular cluster, M22, was discovered in 1665 by Johann Abraham Ihle, a German amateur astronomer (Jones 1991). However it was not until 1789 that William Herschel coined the term globular cluster for such objects in his catalogue of deep sky objects, due to their spherical shape. Many more clusters were discovered subsequently and in the 1830s John Herschel noticed that these clusters tend to occur more in the direction of Sagittarius (Ashman and Zepf 1998). This fact was later used by Shapley, in 1918, to estimate distance of the Solar System from the Galactic Centre with Sagittarius marking the direction. Presently, there are around 157 globular clusters identified in the Milky Way galaxy (Harris 2010). Their distribution is showed in Figure 1.1.

Table 1.1: Typical parameters of globular and open clusters

	Globular	Open
Central density, ρ_0	1×10^4 M$_\odot$ pc^{-3}	10 M$_\odot$ pc^{-3}
Core radius, r_c	1 pc	1 pc
Half-mass radius, r_h	3 pc	2 pc
Tidal radius, r_t	35 pc	10 pc
Central velocity dispersion, σ_0	6 km s^{-1}	0.3 km s^{-1}
Crossing time (line-of-sight), r_h/σ_0	0.5 Myr	7 Myr
Mass-to-light ratio, Υ_R	$2\Upsilon_\odot$	$1\Upsilon_\odot$
Mass	2×10^5 M$_\odot$	3×10^2 M$_\odot$
Number in Galaxy	150	10^5

1.2.2 Cluster Environment

Globular clusters are typically large, compact, spherical star clusters in the outer regions of a galaxy away from the galactic disk. They contain around $10^4 - 10^6$ stars with varying degrees of central condensation. Due to the presence of a stellar density gradient, globular clusters have different radii measurements associated with them, including: the core radius (r_c) where the surface brightness has fallen to half the central value, the half-light radius (r_h) which contains half of the total luminosity and the tidal radius (r_t) which marks the radius at which the galaxy's gravity dominates over the cluster's (Binney and Tremaine 1987). Most of the Galactic globular clusters orbit the Galaxy about the Galactic centre, in orbits not usually lying in the galactic plane, in random orientations. This feature distinguishes them from the open clusters found in the spiral arms of the Milky Way which participate in the Galactic rotation. Also, globular clusters tend to contain old, metal-poor stars while the stars in the galactic disk tend to be metal-rich stars like the Sun. The typical values of some of the parameters for globular and open clusters of the Milky Way galaxy are tabulated in Table 1.1, reproduced from Binney and Tremaine 1987.

1.2.3   Metallicity and Cluster Age

Being simple stellar systems, composed of low metallicity Population II stars leads us to believe that globular clusters are very old objects. The present Universe is thought to be filled by stars of three generations namely, Population III, II, and I, with the oldest (Population III) stars consisting only of hydrogen and helium (first stars to form after Big Bang nucleosynthesis). Population II stars are the metal-poor stars formed from the ejecta of the previous generation of stars while Population I stars are the metal-rich stars like the Sun. The metallicity of a star, *Z*, is defined as the mass fraction of all elements heavier than helium. It is often convenient to express it using the easily observable quantity of iron abundance, [Fe/H],

$$[\text{Fe/H}] = log_{10}\left(\frac{N_{Fe}}{N_H}\right)_{star} - log_{10}\left(\frac{N_{Fe}}{N_H}\right)_{sun} \tag{1.1}$$

where N_{Fe} and N_H represent the number of iron and hydrogen atoms per unit volume, respectively. According to Beers and Christlieb (2005), a star is considered "very metal poor" if it has [Fe/H]< −2.0 and "metal poor" if it has [Fe/H]< −1.0. The majority of the stars in Galactic globular clusters show a homogeneity in the iron-peak (Fe, V, Cr, Mn, Co and Ni) element abundances (Suntzeff 1993; Carretta et al. 2009a) so that [Fe/H] of the overall cluster can be determined by taking a few samples of the constituent cluster stars. The [Fe/H] distribution of Milky Way globular clusters shows a bimodal distribution (as illustrated in Figure 1.2) with [Fe/H] peaks at −1.59 and −0.51 dex, corresponding dispersions of 0.34 and 0.23 dex, respectively (Ashman and Zepf 1998). We categorize the two distinct populations as halo clusters and thick-disk clusters, respectively. The thick-disk clusters have a flattened spatial distribution and rotate about the Galactic Center while the halo clusters have little net rotation and spherical distribution. The bimodal metallicity distribution is seen in globular clusters of almost all massive galaxies (Brodie and Strader 2006).

  The metal-poor stars found in the globular clusters previously helped to determine a lower limit to the age of the Universe. Ages are generally determined by fitting stellar models to the observed Hertzsprung-Russell diagram of the cluster. Carretta
Figure 1.2: The metallicity distribution of Milky Way globular clusters. Also shown are the individual Gaussian fits to the two populations. Image taken from Ashman and Zepf (1998)

et al. (2000) derives the average age of Milky Way globular clusters as 12.9 ± 2.9 Gyr by fitting stellar evolution models to brown dwarfs. Contrastingly, intermediate-age (1-3 Gyrs old) globular clusters have been found in the LMC (see Milone et al. (2009) and references therein). Also, galaxy mergers like the Antennae show young, protoglobular, cloud like objects (Eggers et al. 2005). Hence Milky Way globular clusters can be used to trace its past merger events.

1.2.4   Formation Models

The formation process of globular clusters is not fully understood and remains an open problem in astrophysics. Many theories and models have been put forward which explain the variation of a particular property of clusters but no single theory exists which adequately explains the formation and variation of all the observed properties in a general globular cluster. According to Fall and Rees (1988), these theories can broadly be classified as primary, secondary and tertiary depending on when the clusters formed with respect to the galaxy. Some of these models are discussed as follows.

The primary models suggest the formation of globular clusters before the formation of

the galaxy using a hierarchical clustering model (Peebles and Dicke 1968). Although these models explain the globular cluster luminosity functions (defined as the number of stars in that cluster per unit magnitude) which are observed to be independent of parent galaxy type, they fail to explain the spatial distribution, number, and metallicity of the clusters, which are dependent on the host galaxy (Ashman and Zepf 1998). Also the similarity between stars in the galactic bulge and the thick-disk clusters provide evidence that these clusters could not have formed before the host galaxy.

Secondary formation models suggest globular clusters form contemporaneously to the Galaxy's formation. This is the scenario which has wide acceptance among the researchers in this field due to the presence of a galactocentric gradient in the metallicity of Milky Way globulars (Pilachowski 1984), which provides evidence for the participation of globular clusters in the collapse of the protogalactic cloud. One such model proposed by Fall and Rees (1985) suggests that thermal instabilities in the protogalactic medium lead to the formation of cool gas clouds in pressure equilibrium with the surrounding hot gas. These cool clouds, being of similar mass to the globular clusters ($\sim 10^6 M_\odot$), are identified to be their progenitors. However, the requirement by this model for the cool clouds to maintain a temperature of 10^4 K poses problems. Although this model explains the formation of low metallicity halo clusters adequately it is unable to explain the thick-disk clusters which show higher metal content. Most secondary models also fail in explaining the bimodal distribution seen in the metallicity of the globular clusters.

This leads us to the tertiary models which suggest the formation of globular clusters after the formation of the galaxy. Burkert et al. (1992) proposes that thick-disk globulars are formed in an intermediate step in the collapse of the galactic spheroid to a thin disk. While this may be true, Zinnecker et al. (1988) suggests that globular clusters are the cores of nucleated dwarf ellipticals after their accretion to the host galaxy. This model was proposed after observing certain similarities between the globular clusters and the dense nucleus of dwarf ellipticals. However this model is not able to explain the observed correlations of cluster properties with galactocentric distance and differ-
Figure 1.3: Stellar evolution of a sun like star. Note that the majority of its life time is spent on the main sequence. Image Source URL:http://www.profjohn.com/courses/ast1004/starlives/starlives.htm

ences in the masses between dwarf elliptical nuclei and globular clusters. Also young proto-globular clusters in interacting merger systems (Eggers et al. 2005) provide some evidence for the tertiary models.

1.3 Chemical Enrichment

1.3.1 Stellar Evolution

On large time scales ($\backsim 10^8$ yrs) the passage of the cluster through the galactic disk should sweep out most of the intracluster medium from the globular clusters (Spergel 1991) while on short time scales UV radiation from white dwarfs are efficient in expelling the gas medium (McDonald and Zijlstra 2015a). The tenuous gas medium in

globular clusters is not sufficient to form molecular clouds hence star formation has ceased and evolved stars are the only observable objects in the globular clusters. Although the [Fe/H] value remains the same among the stars in a globular cluster, there are large variations seen in the abundances of light elements: C, N, O, Na and Al within a cluster (Suntzeff 1993) which could be explained by taking a closer look at stellar evolution. Stellar evolution can be traced with the help of the Hertzsprung-Russell (HR) diagram (see Figure 1.3) which is a scatter plot of stellar luminosities against surface temperature.

Star formation begins with the gravitational collapse of molecular clouds where half of the gravitational energy released is lost as radiation and the other half heats up the cloud (Phillips 1999). This is called the protostar. The collapse of the protostar continues until the conditions in the core are favourable for hydrogen fusion to occur. The star enters the main-sequence phase when the hydrogen burning starts in the core and the star attains a hydrostatic equilibrium between gravity and radiation. The mass of the star greatly affects its evolution. Stars of mass less than $1.5M_{\odot}$ (3×10^{30} kg) fuse hydrogen to form helium via the proton-proton (p-p) chain. Heavier stars also fuse hydrogen via the carbon-nitrogen-oxygen (CNO) cycle. Stars spend most of their lifetime in the main sequence, however heavier stars evolve faster as they are more efficient at hydrogen burning. Hence, most of the stars observed today in globular clusters are low-mass ($\backsim 0.8M_{\odot}$), main-sequence stars.

Towards the end of the main sequence (MSTO), the star depletes the hydrogen in its core and hydrogen fusion occurs in a shell around the inert helium core. This changes the equilibrium between radiation pressure and gravity. Thus the star increases its luminosity and cools the surface temperature by expansion of its stellar atmosphere. The star now enters the red giant branch (RGB) phase. The expanding envelope becomes more convective and brings the products of hydrogen fusion up to the surface through deep convective mixing. This is also known as the first dredge-up (FDU). As a consequence this deep mixing would change the light element abundance in the stellar atmosphere.

The core temperature of an RGB star continues to increase due to the gravitational contraction of helium from hydrogen shell fusion. When the core temperature reaches $\sim 10^8$ K helium ignites and fuses rapidly via the triple-α process to form carbon. This is called helium flash and it rapidly increases the core temperature. The carbon in the core could further react with another alpha particle to form oxygen. This process is essential in producing light elements (Li, O, Na, Si, Al, Mg) in stellar cores. The helium fusion expands the stellar core and the overlying layer which causes the hydrogen burning to decrease. The decreased energy output causes the star to contract thereby increasing its surface temperature as the star proceeds onto the horizontal branch (HB) phase. Similar to the previous hydrogen-burning phase, the HB star exhausts the helium in its core and starts fusing the helium in a shell around the carbon and oxygen core. The star then enters the asymptotic giant branch (AGB) phase. Similar to the FDU, a second dredge up occurs when the core is depleted of helium for stars with masses of $4-8$ M$_\odot$. The AGB phase is characterized with more energy output and it asymptotically approaches the RGB in colour-magnitude diagrams. This poses difficulty in distinguishing bright AGB and RGB stars near the RGB tip. Also the outer, hydrogen-burning shell periodically deposits helium into the helium-burning shell and thus causes temporary brightness of the star. This is called as thermal pulsation. This is seen in evolved AGB stars. Additionally, these pulses also help in mixing the intershell regions. These pulsations and the dredge-ups help in bringing the core nuclear fusion products towards the surface. This material is typically carbon rich and forms a carbon star when C/O> 1. However, in globular clusters the stars don't normally experience enough dredge-up for this to happen.

If the mass of the star is approximately $\lesssim 8$ M$_\odot$ then it will not be able to fuse the carbon in its core. The outer layers of such a star will be ejected by stellar winds and form a planetary nebula, while the inert C$-$O core cools and forms a white dwarf. For massive stars the core becomes hot enough to continue nuclear fusion of heavier elements. Consequently the star develops an onion-like structure with the outer layer containing

hydrogen and the inner core made of iron. Nuclear fusion stops at Fe^{56} beyond which the process becomes endothermic.

Elements heavier than iron are formed by the 'r-' (rapid) and 's-' (slow) neutron capture processes. In the s-process, the atom has enough time to β-decay to a lower atomic number. This happens in massive AGB stars. The r-process primarily happens in Type II supernovae where the neutron capture element does not have enough time to β-decay before capturing another neutron. If the mass of the stellar core is less than $\approx 1.4 M_\odot$ (the Chandresekar limit), it will form a white dwarf. Otherwise for heavier cores, the electron degeneracy pressure will not be able to support the gravitational collapse of the star, which will leave behind a neutron star or a black hole after undergoing a supernova. Thus the metals (elements heavier than H, He), blown out to the ISM by the supernova explosion, are recycled and seed the formation of the next generation of stars.

1.3.2   Abundance Patterns

The abundance of elements in stars is mainly found by equivalent width measurement. In this method, a profile (Voigt/Gaussian/Lorentzian) is fitted to an absorption line seen in the star and its normalised area is measured. This is then used in conjunction with local-thermodynamic-equilibrium (LTE) models of stellar atmospheres to determine the element's abundance. The other common method is the spectral synthesis method where radiative equations are solved to generate a model, which can be compared to the observed spectrum. Due to the relatively low metal content and simple spectra seen for stars in globular clusters, the equivalent width method is preferred.

The abundance of iron-peak elements is observed to be same through out the stars in a globular cluster which led to idea that all stars were formed simultaneously (Ashman and Zepf 1998). Also the narrowness of the principle sequences in the observed HRDs of globular clusters were a further proof of their homogeneity. However, inhomogene-
Figure 1.4: The CMD of ω Centauri from the work of Bedin et al. (2004)

ity in the light element abundances were noticed by Cohen (1978); Norris et al. (1981); Suntzeff (1993)

Initially two clusters, ω Centauri and M22, were found to show an inhomogeneity in [Fe/H] (Gratton 1982). Norris et al. (1981) found bimodality in the distribution of CN abundance of stars in NGC6752. Cohen (1978) observed the difference in Al abundance and the anti-correlation between [Na/Fe] and [O/Fe]. Shetrone (1996) also observed an anti- correlation between [Mg/Fe] and [Al/Fe].

Denissenkov et al. (1998) explains the abundance differences on the basis of either an evolutionary scenario or a primordial scenario. The evolutionary scenario proposes that the differences are a feature of deep mixing in evolved stars while the primordial scenario attributes them to chemical enrichment from a previous generation of stars. Due to instrumental limitations, abundance measurements are usually taken only for

the evolved stars in a cluster. However, Gratton et al. (2001) were able to detect the the Na-O anti-correlation in the main-sequence stars of NGC6752, thereby giving proof of the primordial scenario. They also confirmed the Mg-Al anti-correlation.

Bedin et al. (2004) discovered the presence of two main sequence, with unique turn-off points, and two subgiant branches in the colour-magnitude diagram of ω Centauri using the Hubble Space Telescope. The follow-up spectroscopic studies of the stars in the two main sequences revealed that the less-populated blue main sequence (bMS) had a higher metal content than the red main sequence (rMS). This further advanced the proposition of enrichment by multiple generations of star formation. More recently, Piotto et al. (2007) discovered a triple main sequence in NGC2808. Also, due to better resolution of the cameras, multiple sequences of RGBs are also observed (NGC362: Carretta et al. (2013); NGC1851: Milone et al. (2008)). The abundance patterns seen in globular clusters are usually taken as an indication that a second generation of stars has been enriched by material ejected by $5-8$ M$_\odot$ stars because they are rich in s-process elements compared to the first generation. However both populations' chemical abundance patterns reflect those of Type II supernovae ejecta (high [α/Fe] ratios).

1.4   M5

Messier 5 (alternatively NGC 5904) is a globular cluster located in the constellation of Serpens (Dreyer 1888). The cluster is 6.2 kpc from the galactic centre, and has galactic co-ordinates of $l = 3.86$, $b = 46.80$ (Harris 2010). There are no peculiarities (presence of double or splitting of the evolution branches) seen in the CMD of M5. M5 shows a clear separation between the AGB and RGB in its CMD. The horizontal branch morphology of M5 is interesting, as it shows a wide spread in HB colour, which can be traced to a spread in HB mass (Gratton et al. 2010a). The earlier abundance measurements on M5 are tabulated in Table 1.2. Ivans et al. (2001) shows a correlation between the abundances of elements sensitive to proton capture (O, Na, Al) and CN band strength index S(3839) in M5 and an over-abundance of $\alpha-$elements with respect
Figure 1.5: Colour–magnitude diagram of the cluster M5 where the different phases are denoted by letters A through F. to [Fe/H]. Lai et al. (2011) found the abundances of 31 elements in 17 stars of M5. Carretta et al. (2009b) performed a wider study on the Na−O anti-correlation and finds it in M5 using 136 stars.

1.5   Overview of this thesis

This thesis is organised into six chapters. Chapter 2 describes the analysis method used to determine the stellar parameters and the chemical abundance along with a brief description of the softwares used. Chapter 3 tabulates the chemical abundance results

2

Analysis Method

2.1 Observation Data

The stars selected for this study were situated near the RGB tip in the CMD of M5. The spectroscopic data for the 55 stars used in this project were obtained with the Hectochelle instrument, a single-order multi-object spectrograph on the Multiple Mirror Telescope (MMT). The MMT is located on the summit of Mount Hopkins ($\sim$ 2606m. above sea level) in Arizona, USA and has a classical Cassegrain design with a primary diameter of 6.5m. The observations were taken on the nights of 17th May 2014 and 15th June 2014 using the OB26, CJ26, RV31 settings (central wavelengths 6632, 6260, 5230 Å, respectively). The weather conditions were clear with ~1″ of seeing. The filters were setup to have a slow readout in a 2×1 (spatial × dispersion) binning mode. The data were reduced by the SAO telescope data centre's Hectochelle pipeline. The signal-to-noise ratio (SNR) of the OB26 spectra varied from 74 to 13. The majority of the useful lines were present in the CJ26 and RV31 settings.

2.2 Equivalent Width Measurement

The equivalent width (EW) measures the strength of the absorption line in a spectra. It is defined as the width of a rectangle whose area is equal to that of the line profile with
Figure 2.1: Pictorial definition of equivalent width. Image Credit:`www.wikipedia.org`

respect to the continuum, with the height set to the continuum level (see Figure 2.1). Equivalent width is usually expressed in terms of the wavelength unit of the spectrum, in this case angstroms (Å). Mathematically, it is defined as:

$$W_\lambda = \int (1 - \frac{F_\lambda}{F_o})d\lambda \qquad (2.1)$$

where W_λ is the EW, F_o represents the continuum level and F_λ represents the intensity at wavelength λ. Therefore, in order to make accurate EW measurements, we need to know the continuum level and the line profile.

 The EWs were measured using software provided by Christian Johnson. The program, written in PYTHON and FORTRAN, uses the stellar spectrum and an input linelist to select particular absoption lines and measure their EWs by fitting Gaussian profiles to them. The measurement procedure is described as follows:

- First, the star's Doppler shift is removed by comparing the star spectrum with a guide spectrum. The high resolution spectrum of Arcturus by Hinkle et al. (2000)
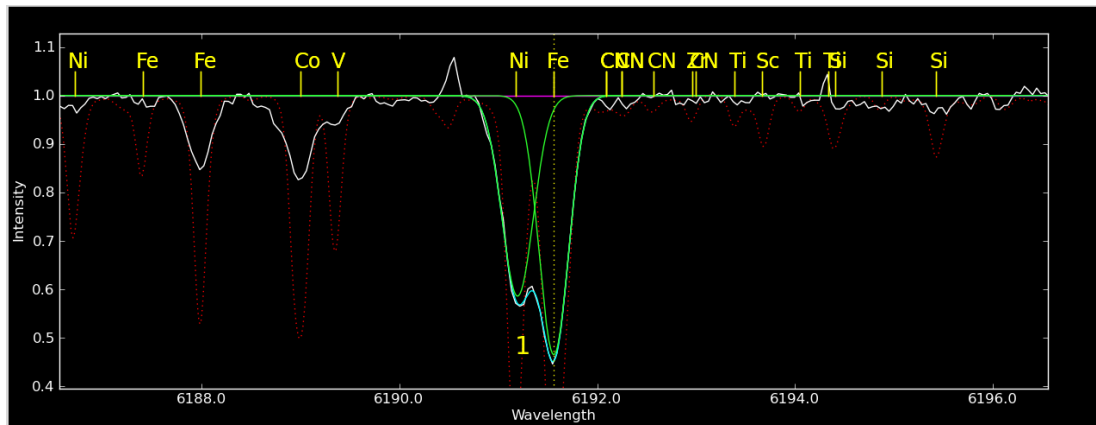

Figure 2.2: The figure shows the EW measurement software interface. The stellar spectrum is shown in white while the reference spectrum is shown in red. The local continuum level is shown by the magenta line. Also shown here is an example of deblending. The iron and nickel lines are close to each other and need to be deblended to get the correct EW. The individual gaussian fits are shown in green and the combined fit is shown in cyan

is used as the guide and a wavelength shift is performed on the star spectrum to match the spectral lines.

- Second, the continuum level of the spectrum has to be set. This is probably the most difficult and important step in measuring the EWs since the value of EW for weak lines is greatly affected by the continuum level (as inferred from equation 2.1). After much discussions and trials, it was agreed upon to set the continuum level locally by distributing the noise points evenly above and below the continuum level.

- Once the continuum is set the program can be used to fit a Gaussian profile individually for the spectral line from the linelist. In cases where the lines were blended, upto five Gaussians can be fit to de-blend lines and obtain the EW for the targeted line (see Figure 2.2).

As a first step, only the Fe I and Fe II line EWs are measured. Table 2.1 shows the linelist used. Care has to be taken to choose lines which have reliable oscillator strength values. For this reason we have chosen a linelist compiled from Johnson et

al. (2012–2015) where these values have been checked against the solar and Arcturus spectra. The program automatically saves the measured EWs in a format which can be readily used by the MOOG software (discussed in the next subsection).

Table 2.1: The full linelist used in this study. The first column gives the line wavelength in Å, the second column gives the ion species, the third column gives the excitation potential (E.P.) for the transition in electron Volts ,and the fourth column gives the weighted oscillator strength for the selected line transition.

2.3   Stellar Parameters

Traditionally Fe I and Fe II EWs are used to determine the stellar parameters: Effective temperature (T_{eff}), Surface gravity (log(g)), and Micro-turbulent velocity (v_t). The

abfind driver from the 2010 versioin of MOOG (Sneden et al. 2012) is used to derive the elemental abundance in $\log(\epsilon)$ notation, ϵ is the number of atoms of that element relative to 10^{12} atoms of hydrogen. It can be converted to [X/H] notation by subtracting the solar value. The MOOG software requires a model atmosphere and the EW tables as input. The output is the average element abundance along with plots of abundance with E.P., reduced EW, and wavelength.

2.3.1 Model Atmospheres

The model atmospheres used in MOOG were created by the α-enhanced ATLAS9 grid (Castelli and Kurucz 2004). These LTE models generally break the stellar photosphere into multiple layers with each layer satisfying both the hydrostatic (pressure–gravity) equilibrium and radiation transfer equations assuming a blackbody source function. In order to get the iron abundance, we first create a model atmosphere with our initial guesses for the stellar parameters.

2.3.2 Abundance dependance with stellar parameters

Equations 2.2 and 2.3 show how Fe I and Fe II abundances are related to T_{eff} and $\log(g)$. These can be derived from the basic Saha–Boltzmann equation as shown in Takeda et al. (2002):

$$\epsilon_{FeI} \propto T_{eff}^{3/2} e^{-(\chi_{ion}-\chi_i)/(kT_{eff})} \tag{2.2}$$

$$\epsilon_{FeII} \propto e^{\chi_i/(kT_{eff})} g^{1/3} \tag{2.3}$$

where χ_{ion} is the iron first ionization potential of 7.9 eV, χ_i is the E.P. of i_{th} level and k is the Boltzmann constant. As inferred from the above equations, Fe I abundance is affected by T_{eff} and almost independent (indirectly dependent through excitation potential) of $\log(g)$ while Fe II line abundance is greatly affected by log(g). Thus we use three conditions to constrain the three parameters.
Figure 2.3: This output window of MOOG show three plots: the top plot is $\log(\epsilon)$ against E.P., the middle plot is $\log(\epsilon)$ against reduced EW, and the bottom one is $\log(\epsilon)$ against wavelength. The cyan line shows the trend while the yellow line shows the mean value.

Excitation Equilibrium : Due to the sensitivity of T_{eff} on ϵ_{FeI}, we constrain it by requiring the FeI abundance to be independent of E.P. over a sufficient range.

Variation with reduced EW : The microturbulence velocity, v_t, is defined as non-thermal component of the gas velocity within the region of spectral line formation (Cantiello et al. 2009). A plot of the equivalent width as a function of the number of absorbing atoms is called the curve of growth. The microturbulence velocity was introduced into the Doppler width of the line opacity function to account for the difference in the calculated and observed line strengths of saturated lines near the flat part of the curve of growth (Takeda et al. 2002). This parameter thus only affects strong lines and can be constrained by making the abundance independent of reduced EWs. Since fewer Fe II lines are measured only Fe I abundance was made to satisfy this condition.

Ionization Equilibrium : Fe II is greatly affected by $\log(g)$ while Fe I is almost independent of it. Thus we impose a condition that the average abundance derived from both Fe I and Fe II to be approximately equal to constrain $\log(g)$.

There may be some outlier points in the MOOG plots which are removed after fixing the T_{eff} and v_t using Fe I lines. The Fe I abundance points which have a difference more than three times the standard deviation are removed and the Fe I abundance is refined before proceeding to match Fe II abundance.

Due to the interdependence of the three parameters we employ an iterative procedure to converge upon the optimal parameters. Once the stellar parameters are found, we proceed onto the measurement of other elements. Figure 2.4 shows the schematic of the method followed.

2.3.3   Stellar Parameters
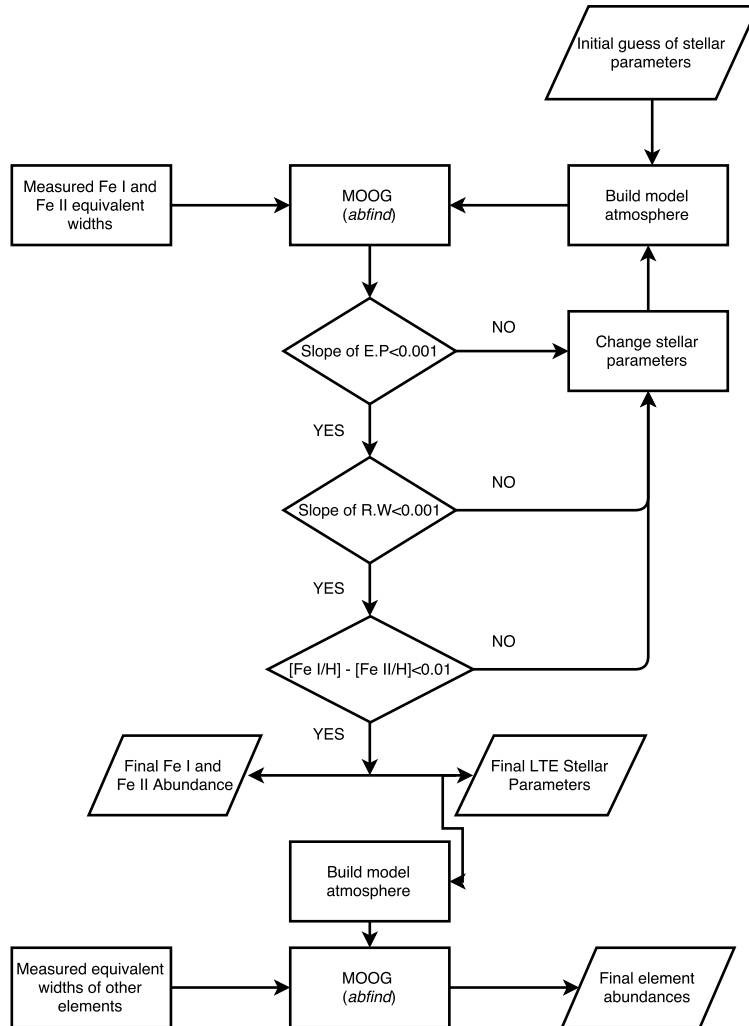

Figure 2.4: A schematic representation of the analysis procedure followed.

Table 2.2: The stellar parameter results are tabulated. The 2MASS identifiers of the stars are used where possible. The errors associated with the measurements are discussed in Chapter 4.

3

Results

The average iron abundance is found to be [Fe/H]= -1.29 ± 0.15 dex. The average [Fe /H] value for the cluster from this study is in agreement with Harris (2010) catalogue value of -1.29 dex. From Table 3.1 we can see that our value is consistent with literature. The differences might be related to different solar values used by the authors however the difference should not exceed 0.5 dex. The relative abundance in this study is calculated using the solar values reported by Asplund et al. (2009). The uncertainties related with the measurements are discussed in the next chapter. The abundance measurements for other elements are summarised in Table: 3.10 (at the end of this chapter).

Table 3.1: Comparison between average [Fe/H] values

Study	[Fe/H]
Ivans et al. (2001)	-1.34 ± 0.01
Ramírez and Cohen (2003)	-1.30 ± 0.02
Lai et al. (2011)	-1.51 ± 0.14
This work	-1.29 ± 0.15
Figure 3.1: Plot of [Si/Fe] versus [Fe/H] with a linear fit.

3.1 Silicon

The [Si/Fe] abundance were meaured for only for 39 stars in this study using four Si I lines. The silicon abundance varies from [Si/Fe]= −0.42 to 0.96. The average value is determined to be [Si/Fe]= 0.16 ± 0.17 dex. This is 0.15 dex lower than the cluster average reported by Ivans et al. (2001), 0.05 dex lower than Ramírez and Cohen (2003) and 0.25 dex lower than Lai et al. (2011). This difference can be attributed to the larger number of Si I lines used by the other studies. Figure 3.1 shows the relation between silicon and iron abundance. We find an anti-correlation between them with a slope of −1.087 with an asymptotic error of ±0.179. Although linear fit might look real due to the low asymptotic error, this trend is affected by the spread in the iron abundance and can be considered as artificial.
Figure 3.2: Plot of [Ca/Fe] versus [Fe/H] with a linear fit.

3.2 Calcium

The [Ca/Fe] abundances were measured for all the stars in this study using six Ca I lines. The cluster average is [Ca/Fe]= 0.13 ± 0.12 dex. It is 0.13 dex lower than Ivans et al. (2001), 0.2 dex lower than Ramírez and Cohen (2003) and 0.16 dex lower than Lai et al. (2011). We also report a bigger error margin than other studies. Figure 3.2 shows the trend of calcium abundance. Like the silicon abundance, we find a gradient with iron abundance with a slope of -0.928 ± 0.134. This trend is quite noticeable here but it is not seen in any of the other studies. The slope is considered to be due to the iron abundance spread.

3.3 Titanium

The neutral [Ti I/Fe] abundance is measured for all the stars in this study using seven Ti I lines. The average value is 0.4 (to match 0.15) dex. This is 0.18 dex higher than Ivans et al. (2001), 0.24 dex higher than Ramírez and Cohen (2003) and 0.21 dex higher than
Figure 3.3: Plot of [Ti I/Fe] versus [Fe/H] with a linear fit.

Lai et al. (2011). This shows a similar behaviour with iron abundance as silicon and calcium but with a lesser gradient of -0.609 ± 0.273 as seen in Figure 3.3. The neutral titanium also shows a larger scatter in abundance than silicon and calcium.

For titanium we were also able to measure the abundance of the ionised species using the 5185.91Å line. We report the cluster average as 0.31 ± 0.13 dex. This is seen to be consistent with Lai et al. (2011) where it is 0.02 dex lower. Although ionization equilibrium condition imposed while determining the stellar parameters should give us the same titanium abundance we see an average difference of 0.13 dex between the neutral and ionised species. Two stars in particular, 15182938+0208275 and 15184164+0203533, have very high differences of 0.99 and 1.32 dex. If they are considered as outliers the average difference comes down to an acceptable 0.08 dex. From Figure 3.4 we see a similar trend, as seen in calcium, having a gradient of -0.943 ± 0.273.
Figure 3.4: Plot of [Ti II/Fe] versus [Fe/H] with a linear fit.

3.4 α Elements

The combined variation of silicon, calcium and titanium should give us a better understanding of the data as it will reduce the scatter in them. The α-element abundance is calculated as $[\alpha/Fe] = \frac{([Si/Fe]+[Ca/Fe]+[Ti/Fe])}{3}$. This is limited to the 39 stars which have all three measurements. Only the neutral ion abundances were used. Figure 3.5 shows that α-elements variation is similar to calcium with a slope of -0.953 ± 0.133. Due to the large scatter seen with iron abundance it is inconclusive whether this trend might be real.

3.5 Chromium

The chromium abundance is found for 42 stars in the sample using the Cr I lines. The average [Cr/Fe] abundance is found to be 0.10 ± 0.41 dex. The main source of error comes from the measurement of the weak 5225.81 Å line. This average value is 0.23 dex higher than Ramírez and Cohen (2003) and 0.17 dex higher than Lai et al. (2011).
Figure 3.5: Plot of [α/Fe] versus [Fe/H] with a linear fit.

Figure 3.6 shows the relation with iron abundance. The linear fit shows a gradient of -0.669 ± 0.211.

3.6 Yittrium

The yttrium abundance is measured for 42 stars in the sample using the Y II lines. The average is [Y/ Fe]=0.01 ± 0.16 dex. This is 0.21 dex higher than Lai et al. (2011). Figure 3.7 shows the trend with iron abundance. It has a slope of -0.684 ± 0.287 with [Fe/H].

3.7 Cerium

The cerium abundance is measured for 34 stars in the sample using the Ce II 5274.23 Å line. The cluster average is [Ce/Fe]= 0.13 ± 0.13 dex. This is 0.23 dex higher than Lai et al. (2011). Figure 3.8 shows the trend with iron abundance. It has a slope of
Figure 3.6: Plot of [Cr/Fe] versus [Fe/H] with a linear fit.
Figure 3.7: Plot of [Y/Fe] versus [Fe/H] with a linear fit.
Figure 3.8: Plot of [Ce/Fe] versus [Fe/H] with a linear fit.

-1.516 ± 0.225. The strong anti-correlation arises as an artefact due to the metallicity spread.

3.8 Neodymium

Neodynium abundance is measured for 40 stars in the sample using the Nd II lines. the cluster average is [Nd/Fe]= 0.52 ± 0.14 dex. This is 0.47 dex higer than Lai et al. (2011). Figure 3.9 show its variation with [Fe/H]. The trend has a slope of -0.892 ± 0.302.

3.9 Erbium

Erbium abundance is measured using the Er II 6170 Å line. The cluster average is [Er/Fe]= 1.27 ± 0.18 dex. This shows a strong anti-correlation with iron abundance with a slope of -1.45 ± 0.825 dex. Figure 3.10 shows its variation with iron abundance. There is a huge scatter in the data.
Figure 3.9: Plot of [Nd/Fe] versus [Fe/H] with a linear fit.
Figure 3.10: Plot of [Er/Fe] versus [Fe/H] with a linear fit.

3.10 Summary

In conclusion all the other element abundances show a consistent anti-correlation with iron abundance but this artificial trend is expected to arise out of the spread in iron abundances. These artificial trends can be diminished by handling errors more rigorously. The mean abundances of [Fe I/H], [Si I/Fe I], [Ca I/Fe I] and [Ti I/Fe I] are considered to be good when compared with the literature values. This study shares 11, 2 and 1 star in common with Ivans et al. (2001), Lai et al. (2011) and Yong et al. (2008), respectively. The differences in the reported and observed stellar parameters are tabulated in Table 3.2.

Error Analysis

4.1 Measurement Error

There are two main sources of errors in the abundance measurements. The first source is due to the statistical nature of measurement. The measurement error (σ_{meas}) is characterised by the errors in EW measurement (placement of the continuum, matching of the observed line profile with a Gaussian profile) and the uncertainties in the atomic parameters. It is calculated by:

$$\sigma_{meas} = \frac{\sigma}{\sqrt{N_{lines}}} \tag{4.1}$$

where σ is the standard deviation around the the average abundance value calculated by MOOG and N_{lines} is the number of EW measurements made for that element. The σ_{meas} for the star with the highest and lowest SNR in the OB26 grating is averaged to give the σ_{meas} for the entire sample. Our sample of stars show a SNR variation of 75 to 13 in the OB26 setting with an average SNR of ~44. Therefore to include the effect of SNR, the total error σ_{tot} for each measurement is weighted by a fraction of the average SNR to the stellar SNR. The SNR values seen in the observed sample is tabulated in Table 4.4. From Table 4.1, we can see that the average measurement errors are well within 0.20 dex for all elements with the exception of Cr. The [Cr/Fe] abundance shows increased uncertainty due to the difficulty in the de-blending and weakness of

Figure 4.1: Plot showing variation of [Fe/H] with SNR. As expected we see a bigger scatter in [Fe/H] for stars with lower SNR. The two star taken as representative for the sample are shown in blue.

Table 4.1: σ_{meas} for the measured lines

Abundances	Star				Observational Error
	15183583+0203421		36

the 5225.8 Å spectral line.

4.2   Error due to Stellar Parameter Uncertainty

The second source of error is due to the uncertainties in the stellar parameters (or model atmosphere) (σ_{atm}). This is calculated by studying the variation of abundance with each stellar parameter separately. Each stellar parameter is perturbed one at a time while keeping the other parameters same and its effect on the abundance is noted. Here again the stars with the highest and the lowest SNR in the OB26 grating were taken as representative of the entire sample. The parameters were perturbed by ±100 K, ±0.6 dex, ±0.20 dex and ±0.25 dex for T_{eff}, $\log(g)$, [Fe/H] and v_t respectively. These were chosen so as to contain ∼ 68% of the variation between the photometric and spectroscopic temperatures within the perturbation step for T_{eff}. A similar argument is made in the choice of the perturbation step in in $\log(g)$, [Fe/H] and v_t where ∼ 68% of the variation between the reported values and observed values fall within our step size. We neglect the correlations between the stellar parameters and approximate them to be independent of each other. So the error due to model atmosphere, σ_{atm}, is given by the quadratic sum of the errors in the individual parameters:

$$\sigma_{atm} = \sqrt{\sigma_{T_{eff}}^2 + \sigma_{log(g)}^2 + \sigma_{[Fe/H]}^2 + \sigma_{v_t}^2} \qquad (4.2)$$

where $\sigma_{T_{eff}}$, $\sigma_{log(g)}$, $\sigma_{[Fe/H]}$, σ_{v_t} are the normailsed errors due to uncertainties in the stellar: temperature, surface gravity, metallicity and micro-turbulence velocity respectively.

The total abundance error is given by:

$$\sigma_{total} = \sqrt{\sigma_{meas}^2 + \sigma_{atm}^2} \qquad (4.3)$$

These uncertainties are reported in Table 4.2. The error in most of the element abundances is less than 0.20 dex and can be summarised as follows:

- The Ca abundance shows the least dependence with stellar parameter uncertainty.

Table 4.2: Uncertainties due to stellar parameters

Abundances	T_{eff}	$\log(g)$	[Fe/H]	v_t	σ_{atm}	σ_{meas}	σ_{total}
	±100K	±0.6 dex	±0.20 dex	±0.25 km s^{-1}	dex	dex	dex
[Fe I/H]	±0.1	±0.01	±0.01	∓0.11	0.15	0.03	0.15
[Fe II/H]	∓0.1	±0.28	±0.07	∓0.07	0.31	0.17	0.35
[Si I/Fe I]	∓0.12	±0.08	±0.02	±0.1	0.17		0.17
[Ca I/Fe I]	±0.02	∓0.05	∓0.02	±0.03	0.06	0.1	0.12
[Ti I/Fe I]	±0.09	∓0.02	∓0.03	±0.01	0.1	0.11	0.15
[Ti II/Fe II]	±0.08	∓0.06	∓0.02	∓0.09	0.13		0.13
[Cr I/Fe I]	±0.06	∓0.03	∓0.02	±0.01	0.07	0.4	0.41
[Y II/Fe II]	±0.1	∓0.05	∓0.01	∓0.04	0.12	0.11	0.16
[Ce II/Fe II]	±0.11	∓0.04	±0.01	±0.05	0.13		0.13
[Nd II/Fe II]	±0.12	∓0.04	∓0.01	±0.03	0.13	0.05	0.14
[Er II/Fe II]	±0.17	∓0.05	∓0.02	∓0.01	0.18		0.18

- The abundance relations of Cr I and Fe II show huge errors. The Cr abundance is limited by the measurement uncertainty while Fe II is limited by stellar parameter uncertainty.

- Effective temperature (T_{eff}) is found to be the dominating factor in the σ_{atm} for most elements except for Fe II.

- Fe II is affected more by $\log(g)$. This is due to the dependence of the Fe II on electron pressure which is sensitive to $\log(g)$.

Table 4.3 compares the abundance dependencies with stellar parameters between this work and Ivans et al. (2001). Note that Ivans et al. (2001) use a smaller perturbation step than our study and care has been taken to characterize the uncertainties of this work with the same perturbation steps for comparison purposes. There is a good overall agreement of the model atmosphere uncertainties with Ivans et al. (2001).

5

Discussion

5.1   Variation of [Fe/H] with Stellar Parameters

The average value of T_{eff} among the stars in this study is 4673 K. The iron abundance exhibits a very small anti-correlation with T_{eff} with a slope of -2.7×10^{-4} with an asymptotic error of $\pm 9.86 \times 10^{-5}$. This is an artificial trend which arises due to the uncertainty in the iron abundance. There is a huge spread in the iron abundance observed in this study which is neither observed in the literature (Carretta et al. 2009b) nor in the HRD of M5. The increased spread in iron abundances among the warmer stars in this study (see Figure 5.1) is probably due to the lower SNR seen in their spectra.

There is a correlation seen in variation of [Fe/H] with $\log(g)$ with the gradient being 0.232 ± 0.038. To derive the iron abundance we use six Fe II lines and 82 Fe I lines (see Table 2.1). The scatter in iron abundance is due to the stellar parameter uncertainties specifically the surface gravity which greatly affects Fe II abundance. This is can be due to $\log(g)$ being taken as a free parameter or the breaking of the LTE condition in some AGB and post-AGB stars. Instead of keeping $\log(g)$ as a free parameter we can derive it using the photometric luminosity as shown in Ivans et al. (2001) but at the expense of the deriving it independently without any assumptions of the stellar mass. Increasing the number of Fe II lines could also help in getting a better estimate of the
Figure 5.1: Plot of [Fe/H] versus T_{eff} with a linear fit.

Figure 5.2: Plot of [Fe/H] versus log(g) with a linear fit.
iron abundances.

Figure 5.3: Plot of [Ti II/Ti I] versus [Ti I/Fe] with a linear fit.

5.2 Determining the correctness of model atmospheres using Titanium abundance

The correctness of the model atmospheres (thereby stellar parameters) can be checked by knowing the [Ti II/Ti I] abundance. Since we imposed ionization equilibrium in our stellar parameters there should be no difference between the two titanium abundances measured. Therefore we expect to see a perfect correlation between [Ti I/Fe] and [Ti II/Fe] but from Figure 5.3 we see a a slope of -0.041 ± 0.115 when we expect a flat line of no slope.

When we plot [Ti II/Ti I] with T_{eff} we find that stars with T_{eff} between 4600 K and 5000 K show an acceptable scatter around the expected value of zero. The stars with low T_{eff} (less than 4300 K) show a huge mismatch in their titanium abundance thus signifying their faulty stellar parameters.
Figure 5.4: Plot of [Ti I/Ti II] versus T_{eff}

5.3 Variation of abundance with radial distance

The distance of the star from the cluster centre is calculated using the ASDC angular distance calculator [1]. The cluster centre has the co-ordinates of RA=$15^h18^m33.22^s$, Dec=+02°04′51.7″ (Harris 2010). Figure 5.5 shows the distribution of projected distances in this study. The stellar distances vary from 0.28 to 23 arcminutes from the cluster centre. The distribution of distances is a combination of actual stellar density convolved with how closely the fibres can be placed in the spectrograph. The stars with distances greater than 8 arcminutes are avoided in the further discussion in this section.

Iron abundance

The iron abundance is plotted against distance from cluster centre in Figure 5.6. The slope of the linear fit is -0.008 ± 0.0152. Overall iron abundance does not show any

---

[1]URL:`http://www.asdc.asi.it/dist.html`

Figure 5.5: Histogram showing distribution of projected distances from the cluster centre

trend with the projected distance from cluster centre.

Silicon

The silicon abundance, [Si/Fe], shows much less spread in its variation with cluster distance. The linear fit has a slope of 0.017 ± 0.027. Due to the uncertainty being of the same order as the slope, the trend is considered to be statistically insignificant. The [Si/Fe] is considered to show no variation with cluster distance as seen in Figure 5.7.

Calcium

This shows a similar behaviour as [Si/H]. The linear fit has a slope of 0.003 ± 0.01 (see Figure 5.8). Due to the large fractional uncertainty in the slope, it can be neglected. Again there is no significant variation seen with respect to distance from the cluster centre.
Figure 5.6: Plot of [Fe/H] versus projected distance from cluster centre with a linear fit.

Figure 5.7: Plot of [Si/Fe] versus projected distance from cluster centre with a linear fit.
Figure 5.8: Plot of [Ca/Fe] versus distance from cluster centre with a linear fit.

Titanium

Figure 5.9 shows the [Ti I/Fe] variation with distance from cluster centre. There is a big spread in the abundance values between 3 and 5 arcminutes due to more number of stars sampled in this region. The linear fit shows a slope of 0.002 ± 0.019. There is no real trend of [Ti I/Fe] with distance in M5.

The [Ti II/Fe] shows a bigger spread than [Ti I/Fe] values (see Figure 5.10). The linear fit has a gradient of 0.019 ± 0.019. There is no real variation seen with distance.

α-Elements

The combined behaviour of silicon, calcium and titanium is reflected in the α-element abundance. The α-elements show a similar variation as [Si/Fe] with distance albeit with much lesser spread. The linear fit has a slope of 0.008 ± 0.011. The result confirms the absence of any real trend in the [α/Fe] variation with distance.
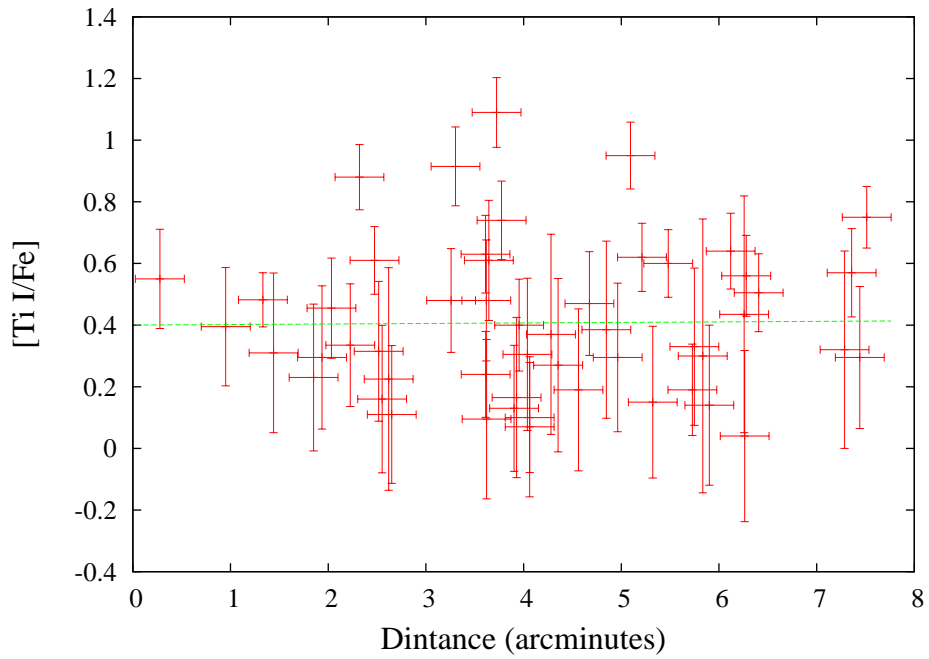

Figure 5.9: Plot of [Ti I/Fe] versus projected distance from cluster centre with a linear fit.

Figure 5.10: Plot of [Ti II/Fe] versus distance from cluster centre with a linear fit.

Figure 5.11: Plot of [α/H] versus distance from cluster centre with a linear fit.

Other elements

Figures 5.12, 5.13, 5.14, 5.15, 5.16 shows the variation of [Cr/Fe], [Y/Fe], [Ce/Fe], [Nd/Fe] and [Er/Fe], respectively. The corresponding gradients seen in them are 0.019 ± 0.015, -0.017 ± 0.02, -0.008 ± 0.02, -0.014 ± 0.021 and -0.097 ± 0.062, respectively. The corresponding slopes are statistically insignificant due to high relative uncertainty in them. Therefore no real trends are seen in the variation of any element with distance.

5.4 Comparison with photometry

The effective temperatures obtained from MOOG (Section 2.3.3) are compared with the photometric temperatures of M5 from McDonald et al. (in preparation). The photometry values were derived from several sources:

- Optical UBVRI photometry are taken from Viaux et al. (2013).

- Optical g- and i-band photometry from Sloan et al. (in prep.).

Figure 5.12: Plot of [Cr/Fe] versus distance from cluster centre with a linear fit.

Figure 5.13: Plot of [Y II/Fe] versus distance from cluster centre with a linear fit.

Figure 5.14: Plot of [Ce II/Fe] versus distance from cluster centre with a linear fit.

Figure 5.15: Plot of [Nd II/Fe] versus distance from cluster centre with a linear fit.
Figure 5.16: Plot of [Er II/Fe] versus distance from cluster centre with a linear fit.

- Near-infrared photometry from 2MASS Cutri et al. (2003).

- Near-infrared photometry from Valenti et al. (2004).

- Archival mid-infrared photometry from the *Spitzer Space Telescope*, reduced by Martha Boyer.

These were combined using the spectral-energy distribution fitting method described in McDonald et al. (2012). Effective temperatures and luminosities were calculated assuming [Fe/H] = −1.29 dex, a stellar mass of 0.80 $M_\odot$, a distance of 7.5 kpc, and interstellar reddening of E(B-V) = 0.03 mag following the reddening law used in McDonald et al. (2012).

The differences are tabulated in Table 5.1. On average the spectroscopic temperatures are ∼ 33 K higher with respect to the photometric ones. There is also a large variation in the Δ T_{eff} value with the standard deviation being 213 K. Three stars in particular show huge differences between their photometric and spectroscopic temperatures: 15182245+0202242 ($\Delta T_{eff}^{spect.-phot.}$=396 K, 15183280+0204362 ($\Delta T_{eff}^{spect.-phot.}$=525 K)

and 15181445+0203131 ($\Delta T_{eff}^{spect.-phot.}$=1083 K). These stars may be photometrically confused. Ignoring them, we find the new average and standard deviation in $\Delta T_{eff}^{spect.-phot.}$ of −4 K and 132 K. The photometric error These results show a good agreement between the two values. These errors are consistent with other errors in the stellar parameters.

Table 5.1: Comparison between photometric and spectroscopic temperatures

5.5 Variation between AGB and RGB star mass

The typical mass of an RGB star is ~0.84 $M_{\odot}$ (McDonald and Zijlstra 2015b) while the mass of an AGB star is typically ~0.63 $M_{\odot}$ (Gratton et al. 2010b). Hence we should expect the AGB star masses to be ~25% lower than the RGB stellar masses. We follow a similar procedure to that outlined in McDonald et al. (2011) to differentiate between AGB and RGB stars based on their masses using:

$$M = \frac{gL}{4\pi\sigma T_{eff}^4 G} \tag{5.1}$$

where g is the surface gravity (spectroscopic), L is the stellar luminosity, σ is the Stefan-Boltzmann constant, T_{eff} is the effective temperature (photometric) and G is

the gravitational constant. This can be modified to:

$$\frac{M}{M_\odot} = \frac{(g/g_\odot)(L/L_\odot)}{(T_{eff}/T_\odot)^4} \tag{5.2}$$

to obtain stellar mass in solar units. The T_{eff} used is the average of photometric and spectroscopic temperature, the value of $\log(g)_\odot$ is taken to be 4.44 cm s^{-2} and $T_\odot$ is taken to be 5778 K. Figure 5.17 shows the CMD of our sample (excluding the three stars which are considered to be photometrically confused) prepared using data from McDonald et al.(in preparation). The RGB and AGB are spearated by eye inspection as it shows a well separated branches. We would like to find the masses of these stars and find how they vary in the RGB and AGB. Figure 5.18 shows the variation of derived masses of AGB and RGB. The average mass of RGB is 1.44 M$_\odot$ while the AGB average mass is 0.22 M$_\odot$. The average error in the mass is 0.66 and 0.12 M$_\odot$, respectively. This indicates a huge error in mass and hence not used to calculate the mass loss during the RGB evolution. However despite the error in absolute masses we can see a distinction between RGB and AGB stars in Figure 5.18. There's a systematic over-prediction of T_{eff} from spectrocopy for RGB stars while AGB stars show an under-prediction. The average value of ΔT_{eff} between spectroscopy and photometry for RGB and AGB stars is 63 K and -133 K, respectively. This could systematic offset could be responsible for the huge errors seen in the derived masses.
Figure 5.17: CMD of sample stars. RGB star are represented by red while AGB stars are represented by green.

Figure 5.18: Variation of derived mass for RGB (red) and AGB (green)

6

Conclusion

The Stellar parameters and iron abundances are found for 55 stars (AGB and RGB) in the galactic globular cluster M5. We also report the abundances of silicon, calcium, titanium, chromium, yttrium, cerium, neodymium, and erbium. The cluster averages for the present sample in tabulated in Table 6.1. The average iron abundance is found to be consistent with the reported values. A spread in the iron abundance is noted for this sample of stars. This is due to the low SNR in the spectra. A correlation is seen between [Fe/H] and $\log(g)$ which suggests that surface gravity obtained might not be accurate for all the star in this sample. We verify the correctness of the stellar parameters by checking for the ionization equilibrium betwee Ti I and Ti II. We see systematic error in [Ti I/Ti II] for stars with T_{eff} lower than 4400 K.

The best comparisons of with the literature is given in the following list:

- The [Si/Fe] found in this study is 0.05 dex lower than Lai et al. (2011).

- [Ca/Fe] is 0.13 dex lower than Ivans et al. (2001).

- [Ti I/Fe] is 0.18 dex higher than Ivans et al. (2001).

- [Ti II/Fe] is consistent with Lai et al. (2011).

- [Cr/Fe] 0.17 dex higher than Lai et al. (2011).

Table 6.1: Average values of [X/Fe] found in this study. Note the iron abundances are given relative to H.

Element	Value	σ_{tot}
	dex	dex
Fe I	−1.29	±0.15
Fe II	−1.29	±0.35
Si	0.16	±0.17
Ca	0.13	±0.12
Ti I	0.4	±0.15
Ti II	0.31	±0.13
Cr	0.10	±0.41
Y	0.01	±0.16
Ce	0.13	±0.13
Nd	0.52	±0.14
Er	1.27	±0.18

- [Y/Fe] is 0.21 dex higher than Lai et al. (2011).

- [Ce/Fe] is 0.23 dex higher than Lai et al. (2011).

- [Nd/Fe] is 0.47 dex higher than Lai et al. (2011).

An anti-correlation is seen with iron abundance for all the other elements. This is not reported in any of the previous studies and is considered to be artificial, arising due to the [Fe/H] spread. It would be interesting to further study the abundance variation of other α-elements such as Mg and Na. No trend is observed between any of the abundance ratios with the projected distance from the cluster centre.

The spectroscopic temperature obtained is found to be comparable to the photometric temperatures with a few exceptions. On average, the spectroscopic temperatures are 33 K higher than the photometric temperatures for the entire smaple.

The derived masses of the RGB and AGB stars are not accurate enough to calculate the mass loss in the RGB evolution. The systematic offset between the photometric and spectroscopic temperature may be the cause of the uncertainty. The average difference between the spectroscopic and photometric temperatures for RGB and AGB stars

based on our classification is 63 K and -133 K respectively. However we can still see a distinction between the RGB and AGB stars the derived mass plot.

Although we were not able to study the variation of element abundances among individual stars, due to the lack to high signal-to-noise ratio in the spectra, we find reasonably accurate cluster averages for certain elements which agree with the literature. Our accuracy could be increased by determining stellar surface gravity (log(g)) from photometry and using non-LTE methods. Increasing the number of Fe II lines could also help in reducing the scatter in iron abundances. A enhancement of α-elements is not clearly seen in our work and it would be interesting to investigate the abundances of other *alpha*-elements such as magnesium (Mg), aluminium (Al), sodium (Na) and oxygen (O) in our sample. The presence of α-enhancement would hint strongly at the presence of second-generation AGB stars in M5.
