Site-specific factors in the production of local urban ecosystem services: a case study of community-managed green space.

Abstract

Pockets of green space in cities can provide important ecosystem services for urban residents. As naturalistic spaces in urban areas become increasingly sparse, communities are beginning to co-manage existing incidental pockets of land towards the creation of communal natural resources. Such green commons can be productive in terms of ecosystem services through targeted management such as in the case of urban agriculture. Although some work has been done to explore the motives behind and potential benefits of informal green space management, further research is required to understand those characteristics of site management and community input which contribute to the enhancement of site-specific ecosystem service production. A case study of ten examples of community-managed green space was undertaken to evaluate the contributory factors relating to site character and management which influenced productivity as defined by the cumulative provision of four urban-relevant ecosystem services. The analysis revealed that the level of community involvement, measured as intensity of volunteer hours, was highly instrumental in the productivity of sites. Food production also proved to be catalytic for the enhancement of ecosystem services whereas extent of vegetative cover and increasing site size were, counter-intuitively, detrimental to overall site productivity. The study therefore supports the promotion of participatory approaches to the management of ecosystems services in urban areas, particularly those which take small-scale urban agriculture as a primary practice.

Introduction

Collaborative approaches to environmental stewardship through stakeholder management of ecosystems and the ecosystem services they provide have been given increasing support (Krasny and Tidball, 2015). Public stewardship and participation in nature-based activities were highlighted in the UK National Ecosystem Assessment (UK NEA) report (2011) as significant contributors to both human and environmental health and well-being. In that report it is stated that “a key knowledge gap regarding education and ecological knowledge goods concerns the processes by which adults acquire ecological knowledge, their participation in nature-based educational activities and how knowledge acquisition is influenced by engagement with environmental settings as a form of cultural service” (UK NEA, 2011, p.83). The authors of that report also highlighted, and recommended, increasing public participation in the management of ecosystems. Community-led ecological initiatives aimed at environmental education and stewardship can go some way to bridging the disconnect that exists between humans and the environment (Miller, 2005). The promotion of environmental awareness and opportunities for positive human-nature interactions may help to reverse this trend and create more environmentally conscious communities and cities. Stakeholder involvement has likewise been promoted through international policies (CBD, 2001; MEA; 2005) which call for the appropriate decentralisation of natural resource management towards more localised and flexible stewardship of ecosystems and the services they provide. These assertions are echoed in the scientific literature where collective management of urban green commons by urban residents has been posited as one social-ecological measure that may be key in the building of more resilient cities in light of the major challenges they face (Ernstson et al., 2008; Biggs et al., 2010; Colding and Barthel, 2013). Civic ecological intervention has been promoted as an effective way of creating and preserving green infrastructure in urban areas (Krasny and Tidball, 2015). Such collaborative approaches to green space management therefore support the UK government’s goal to

promote green infrastructure in urban landscapes as outlined in the 2011 Environment White Paper (Defra, 2011).

Given these recommendations and that the actual benefits of stakeholder-led stewardship of urban spaces remain unclear, an understanding of the actual situation regarding the development and benefits of community-led ecological stewardship represents a contemporary research imperative.

Participatory approaches to management of urban green commons

Previous studies have highlighted the potential of collaboratively managed urban green space to deliver diverse benefits such as personal well-being and social capital (Hynes and Howe, 2004; Pudup, 2008; Krasny and Tidball, 2015), community cohesion (Okvat and Zautra, 2011) and crime reduction (Kuo et al., 1998). Studies have demonstrated that the stewarding of local urban nature also promotes a sense of place among communities (Stedman, 2003; ODPM, 2004; Kudryavtsev et al., 2012; Tidball and Stedman, 2013) which in turn builds on individual and community well-being.

Barthel et al., 2010 have championed community-horticulture as an important medium for the building of social-ecological memory and adaptive capacity, a theme echoed in studies into civic ecology (Krasny and Tidball, 2015). Although there is much evidence to support these claims, there is a paucity of research which examines such benefits through the lens of ecosystem services. In this regard, the unique productivity of collectively managed green space is often overlooked by local planning authorities (Francis, 1987) in favour of more familiar urban green space types such as municipal parks and nature reserves. Work has been carried out which demonstrates that stakeholder managed gardens exhibit greater biodiversity than more conventionally managed urban green space types (Orsini et al., 2014; Lin et al., 2015; Speak et al., 2015) and that biodiversity increases proportional to levels of user participation (Dennis and James, 2016). However, the benefits issuing from participatory approaches to green space management have yet to be effectively investigated as comprising discrete ecosystem services, nor the relationships between such services.

Ecosystem Services in Urban Areas

Bolund and Hunhammer (1999), in one of the earliest works on urban ecosystem services, stated that, although all people regardless of whether they live in urban or rural areas are dependent on global ecosystems, “The quality of life for urban citizens is improved by locally generated services, e.g. air quality and noise levels that cannot be improved with the help of distant ecosystems.” (p. 8). Despite such locally derived benefits from urban ecosystems, the authors of the Millennium Ecosystem Assessment (2005) chose largely to ignore the urban landscape and cities are generally seen as the recipients rather than producers of ecosystem services (Krasny and Tidball, 2015). Urban areas can however harbour biodiverse habitats (Smith et al., 2006; Davies et al., 2009; Goddard et al., 2010; Cameron et al., 2012) and, through forms of social-ecological innovation and civic engagement, provide ecosystem services in the form of pollination (Strauss, 2009), food production (Saldivar and Krasny, 2004; Lawson, 2005) and education (Krasny and Tidball, 2009).

Notwithstanding the presence of these potential gains from urban nature, the majority of research into urban ecosystem services has focused on those accruing to human well-being stemming from living in proximity to green space (Kaplan, 1995; de Vries et al., 2003; Jackson, 2003; Maas et al., 2006; Maller et al., 2006) and interacting with urban nature (Bird,

2007; Tzoulas et al., 2007; Marselle et al., 2014; Carrus et al., 2015); with larger scale studies concentrating on recreation, climate mitigation and water attenuation services (van der Ploeg and de Groot, 2010; UK NEA, 2011).

The need to evaluate trade-offs, and synergies, associated with the provision of ecosystem services has been presented as a current management imperative in social-ecological systems (MEA, 2005) and, to this end, studies on urban ecosystems services have been carried out (e.g., Nelson et al., 2009; Power, 2010; Raudsepp-Hearne et al., 2010; Haase et al., 2012; Howe et al., 2014). Such studies document relationships between services at the landscape scale, but fail to address design or management considerations contributing to the productivity of urban green space types. Therefore, a better appreciation of on-the-ground service production by, as well as the use and management of, green assets in urban social-ecological systems is still required.

Sites of amenity green space in urban areas have been presented as being important to urban-relevant ecosystem services (Barthel et al., 2010; Niemelä et al., 2010; Ernstson, 2013), though attempts to quantify those services are few and the mechanisms which influence the productivity of such spaces are still little understood. Furthermore, at small scales of natural resource management, such as in the case of urban green space, little is known about the influence of design and management on productivity in terms of ecosystem services. Approaches to management of these green assets are diverse, especially in the case of informally-managed spaces such as community gardens and allotments, and little is understood about the characteristics of informal approaches to urban land use which contribute to the production of ecosystem services. Although the UK NEA Synthesis Report (2011) promotes a participatory approach to natural resource management, it provides little evidence of the mechanisms by which such an approach may effectively manage ecosystem services. The benefits of initiatives involving inclusive, stakeholder-led management of urban green space have been clearly asserted in the literature (Barthel et al., 2010; Ernstson, 2013) but as yet little work has been done to articulate such benefits as specific ecosystem services. Neither has there been any attempt to identify design or management approaches which may be synergistic with the production ecosystem services related to such innovative forms of green space management. Accordingly, the need for an increase in the body of research into ecosystem services production in urban areas was one of the key findings of the UK NEA (2011).

In order to address this gap in knowledge, a case study of ten informal, community-managed green space sites, covering four discrete management approaches, in the Greater Manchester area were examined. The sites were assessed across four ecosystem services (microclimate regulation, food yield, biodiversity potential, and education and well-being) and an evaluation was carried out on the contribution made to overall productivity of case studies by selected physical and management characteristics (vegetation cover, food cultivation area, genera richness, volunteer input, and site size) of the case study sites.

Study area

The study took Manchester, Salford and Trafford, three adjoining metropolitan districts in the Greater Manchester area, as its focus. This urban zone contains multiple examples of collaboratively managed urban green space (AfSL, n.d.; Dennis and James, 2016) which stem from a strong historical prevalence of social-ecological activism (Ritvo, 2010). Ten examples

of autonomous, stakeholder-managed green space associated with four discrete management approaches were selected for the study. Case study locations within the study area are shown in Figure 1 and site descriptions are presented in Table 1.

Figure 1 Location of the case study sites

Table 1 Case study sites and descriptions

<i>Sites</i>	<i>Description</i>
<i>a, b, c</i> (community gardens)	Multi-functional green space in residential areas. Some emphasis on food cultivation and horticulture, variety of design approaches and size (500m ² -1500m ²).
<i>d, e, f</i> (community allotments)	Communal plots on established allotment sites under collective management (600m ² -1000m ²).
<i>g, h</i> (community orchards)	Spaces dedicated primarily to cultivation of soft or hard fruit. Occurring in extensive communal recreational areas (1000m ² – 2000m ²).
<i>i, j</i> (pocket parks)	Small (< 300m ²) sites subject to high levels of surface sealing. Highly improvised. Innovative approaches to site greening (e.g. green roofs/façades, raised bed systems).

Methods

Sites were assessed across four urban-relevant ecosystem services as suggested in the associated literature: microclimate regulation (Bolund and Hunhammer, 1999, van der Ploeg and de Groot, 2010; UK NEA, 2011; Aubry et al., 2012) food yield (Barthel et al., 2011; UK NEA, 2011; Krasny and Tidball, 2015), biodiversity potential (Goddard et al., 2010; UK NEA, 2011; Dennis and James, 2016), and education and well-being (Hansmann et al., 2007;

Krasny and Tidball, 2009; UK NEA, 2011). These ecosystem services were assessed individually for each case study site through field surveys and consultations.

Microclimate regulation

Microclimate regulation was evaluated using the Green Infrastructure (GI) Toolkit developed by Green Infrastructure North West in the UK. The tool provides a score based on the proportion of a given site which can be deemed as ecologically effective and is determined by the extent of both horizontal and vertical vegetative and artificial structures. The basic premise of the tool is to create a score ranging from zero to one based on the surface area cover types as well as secondary and tertiary layers (made up of structural elements such as shrubs, trees, green roofs/walls and water harvesting systems). The resulting score, ranging from 0 to 1, represents the proportion of a site which can be considered ecologically effective. For highly stratified, structurally diverse sites scores greater than 1 are possible. The tool was developed in Berlin as the *Biotope Area Factor* tool (Becker and Mohren, 1990) and modified by planning authorities in Sweden where it was adapted in 2001 for the Malmö *Green Space Factor* (Krause, 2011). The Malmö Green Space Factor was adopted almost seamlessly in the UK by Sutton and Southampton councils and subsequently modified to some degree by the North West Development Agency resulting in the development of the Green Infrastructure Toolkit (Green Infrastructure North West, 2010). Data were collected from each site through field measurements during detailed site surveys and attributing the relevant surface type designated within the GI toolkit to that observed on-site. The data were then entered directly into the GI toolkit work sheet.

Data were collected during site surveys which were carried out between April and September 2013. On each occasion, a single site visit was sufficient to complete the assessment.

Food production

Food yield was projected using proxy figures adapted from other studies of productive community-managed urban gardens (Vitiello and Nairn, 2009) and from UK horticultural datasets (Defra, 2013). A proxy for vegetable crop cultivation was calculated from data acquired from the Philadelphia Harvest Report of community-managed urban vegetable gardens (Vitiello and Nairn, 2009). In the case of orchards and other sites partially designated to fruit production, projected yields per square metre were calculated from the UK government Basic Horticultural Statistics dataset (Defra, 2013). Where fruit production was evident, crop yields were estimated based on whether soft or hard fruits were in cultivation. For hard fruit, average orchard yields per square metre were calculated (as mean UK commercial yields 2007 – 2011: Defra, 2013) and used as a proxy. For soft fruit, a proxy value was calculated as the mean of national soft fruit yields 2007 – 2011 (Defra, 2013). Data for food production at each site were collected simultaneously as part of the survey carried out for microclimate regulation in which each surface cover type was recorded in detail.

Biodiversity potential

The biodiversity assessment employed was developed at the University of Salford (Tzoulas and James, 2010) and focusses on vegetation structure through the use of biodiversity surrogates, Tandy's Isovist technique and the Domin scale (Sutherland, 1996). This provides a rapid assessment method of biodiversity for use in urban environments. In the assessment, the percentage cover of each type of vegetative structure (defined using categories developed by Freeman and Buck (2003)) is estimated using a method adapted from Tandy's

Isovist technique (Westmacott and Worthington, 1994). This measure is then combined with the number of genera of vascular plants recorded to give a combined score for overall biodiversity. Although straightforward in approach the method gives accurate, comparable biodiversity measures for a variety of green space types. A fuller explanation of the background to the biological surrogates and scales used in the method as well as the rationale of the scoring system can be found in Tzoulas and James (2010). Biodiversity assessments were carried out in fair weather conditions during the summer months June to August 2013. Each site assessment for biodiversity potential was carried out as a single visit. The assessments thereby constituted a snapshot perspective, which was consistent with the evaluation of food production and microclimate regulation.

Education and Well being

Data were gathered on cultural ecosystem services through the application of selected indicators from Natural England's monitoring and evaluation protocols for the socio-cultural benefits that individuals and communities receive from interaction with quality green space (Natural England, 2014). These were *Volunteer Hours* and *Educational Visits*. Volunteer hours, relating specifically to physical activity at case study sites (as total hours month⁻¹), were recorded; data relating to administration activities were not included in the analysis. The number of educational and community events which take place at each site over the course of a year was equally recorded as an additional measure of cultural ecosystem services provision following the rationale of the Natural England protocols. As such, these data, when summed, served as proxy measures for the contribution to community education and well-being provided by each site based on the Natural England protocols.

Data pertaining to education and well being were collected from site managers/project facilitators via correspondence or during site visits according to access and availability of sources. This element of data collection was therefore conducted in a more ad-hoc fashion than for other ecosystem service assessments over a period spanning March 2013 to December 2013.

Measures of overall ecosystem service provision

The relative contribution of each site to the total ecosystem service provision for the case study was calculated. Data collected from the ecosystem service assessments were standardised by site area to give a measure of site productivity (as values 100m⁻²). Using the standardized values obtained from the ecosystem service assessments of case study sites, the contribution made by each site to the case study total for each service was calculated as a percentage. Subsequently, site percentage contribution towards each of the selected services (n =4) for the case study were summed to give a measure of cumulative service provision. For each site, the resulting *cumulative provision score*, served to reflect the relative level of productivity of each site in the case study as a measure of service provision per unit area. This process resulted in a standardised dataset with which it was possible to explore with confidence correlations between total service provision and underlying site characteristics. The subsequent calculation of the cumulative provision score, as a grand score reflecting site productivity, provided an effectively continuous variable for use in statistical analyses of site attributes and overall performance.

Data analysis

These data were explored by evaluating synergies and trade-offs between particular site characteristics as well as the effect of those characteristics on the cumulative provision score

of each site. In keeping with the spatially-oriented approach, all values were standardised by site area. The site characteristics used in the analysis were: food cultivation area (percentage cover), genera richness 100m^{-2} , volunteer hours $\text{month}^{-1} 100\text{m}^{-2}$, and percentage vegetation cover. These attributes were selected on the basis that they were all principle components of site design and each a key contributory factor in the tools used to measure individual service provision (food yield, biodiversity potential, education and well-being, and microclimate regulation respectively). In the case of vegetation cover, this characteristic was defined as the total site area where vegetative features were connected to the underlying soil substrate (as opposed to containers or raised beds for cultivation) as defined by the GI toolkit used in the microclimate regulation assessment.

Attributes which were measured as percentages all contained several scores below 20% and were therefore normalised via arc sine transformation prior to inclusion in the analysis. Given that site productivity and characteristics were measured using values standardised by site size, total site area was also included among the site attributes in the analysis as a characteristic which had bearing on overall service provision. Pearson's product-moment correlation tests and regression analyses were performed in SPSS.20.

Results

Site Contributions to Service Provision.

The cumulative provision score of each site (expressed as a percentage), broken down by individual services, is presented in Figure 2.

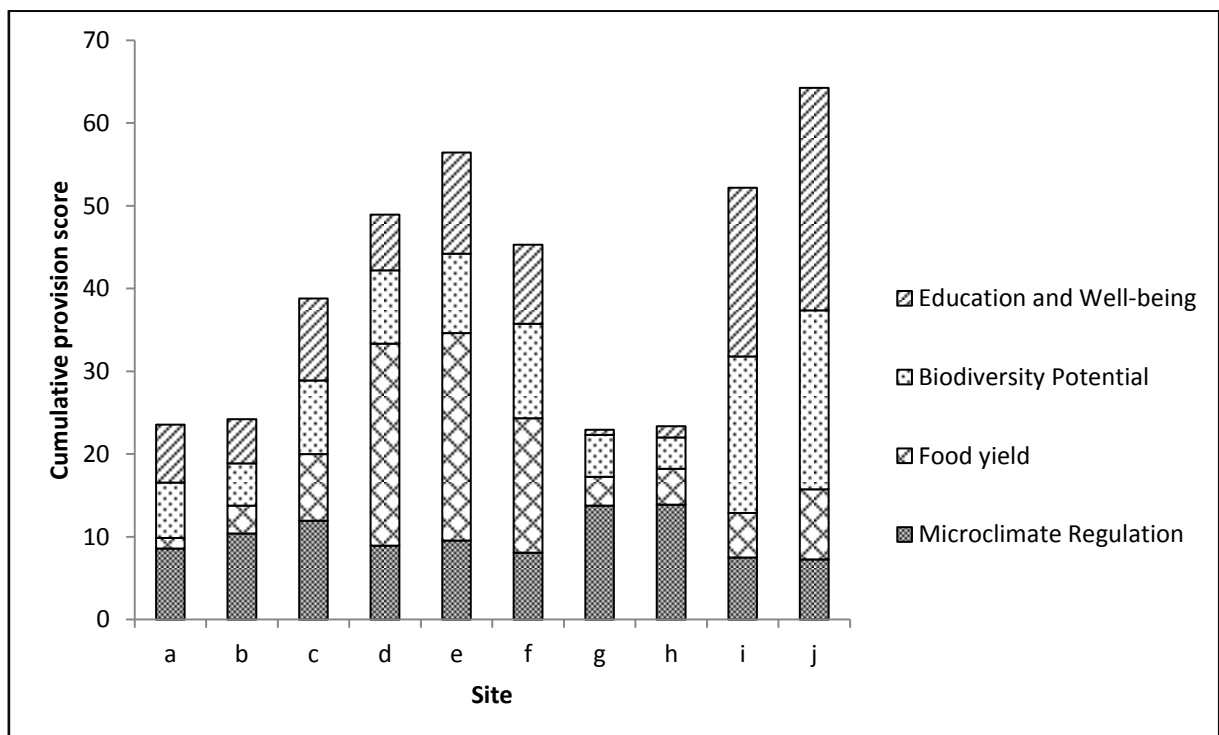

Figure 2. Site contributions to case study cumulative provision score.

Relationships between site characteristics and productivity

Correlations between site characteristics and cumulative provision score are presented in Table 2.

1 **Table 2. Site characteristic relationships (all parameters entered as values 100m⁻²).**

		Genera richness 100m ⁻²	Volunteer hours month ⁻¹ 100m ⁻²	Area food cultivation	Total area	Cumulative provision score
Vegetation cover	Pearson Correlation	-0.836**	-0.705*	0.239	0.659*	-0.673*
	Sig. (2-tailed)	0.003	0.023	0.506	0.038	0.033
	N	10	10	10	10	10

3 *** Correlation is significant at the 0.05 level (2-tailed).**

4

5 Of the correlation values between site characteristics and relative to site cumulative
6 provision score, volunteer hours month⁻¹ 100m⁻² (r² = 0.75; p = 0.001) exhibited the highest
7 positive correlation with cumulative provision score. In terms of between-characteristic
8 relationships, genera richness 100m⁻² correlated positively with volunteer hours month⁻¹
9 100m⁻² (r² = 0.85; p < 0.001), and, counter-intuitively, negatively (r² = 0.70; p = 0.003) with
10 percentage vegetation cover. To gain an understanding of the influence of volunteer effort
11 on biodiversity potential a linear regression was performed with volunteer hours month⁻¹
12 100m⁻², as the predictor variable. The relationship is visualised in Figure 3.

13

15

26

27

According to the regression analysis, site volunteer input accounted for 85% of the variation in site genera richness 100m⁻², with a beta coefficient of 0.923. Overall, the genera richness 100m⁻² score bore the greatest and most significant correlation with cumulative percentage contribution and as such appeared to be the most indicative of the site characteristics contributing to overall service provision. Volunteer hours also demonstrated considerable synergy to cumulative provision score. From these associations it was deduced, particularly given the context of sites as community managed spaces, that site output was highly influenced by human input. As such, they were to a large extent a direct result of volunteer effort, as denoted in the strong correlation observed in Table 2 between volunteer hours and site cumulative provision score (and visualised in Figure 4).

29

30 **Figure 4. Regression of site volunteer effort against cumulative service provision score;**
 31 **p = 0.001.**

32

33 The spatial dimension of site design in particular proved to be instrumental in the efficiency
 34 of ecosystem service provision observed in the case study, site size clearly having a strong
 35 bearing on overall productivity (Figure 5).

48 **Figure 5. Site area and cumulative provision score regression (p = 0.009)**
49

50 In order to control for between-characteristic associations and clarify synergistic effects of
51 each of these on overall performance, analysis was conducted, by way of multiple
52 regression, to delineate the relative effect of site attributes on productivity. The
53 independent variables: percentage vegetation cover, genera richness 100m⁻², volunteer
54 hours month⁻¹ 100m⁻² and percentage area cultivated for food were entered into a
55 backwards conditional regression model (SPSS.20). The results of the regression model
56 demonstrated that these variables were responsible for almost all of the variation observed
57 in the overall relative performance by sites, with an r-squared value of 0.98 (p < 0.001). The
58 output of the test revealed that, although genera richness 100m⁻² demonstrated a high
59 correlation with overall performance (Table 3), this variable was removed from the final
60 model (p = 0.108). Moreover, of the remaining variables in the final model, area of food
61 cultivation exhibited strong partial and semi-partial correlations with cumulative provision
62 score despite not having demonstrated significance in the Pearson's product-moment
63 correlation analysis (Table 2). Vegetation cover exhibited a negative relationship with overall
64 productivity. These relationships are summarised in Table 3.

72 **Table 3. Site attribute multiple regression statistics. Dependent variable: cumulative**
 73 **provision score.**

Model	Unstandardized Coefficients		Standardized Coefficients	t	Sig.	Correlations		
	B	Std. Error	Beta			Zero-order	Partial	Semi-partial
1 (Constant)	33.511	6.927		4.838	0.005			
Volunteer hours month ⁻¹ 100m ⁻²	0.503	0.087	0.945	5.792	0.002	0.863	0.933	0.348
Vegetation cover	-0.345	0.078	-0.448	-4.444	0.007	-0.673	-0.893	-0.267
Genera richness 100m ⁻²	-0.707	0.361	-0.379	-1.955	0.108	0.771	-0.658	-0.117
Area food cultivation	0.700	0.096	0.458	7.267	0.001	0.343	0.956	0.437
2 (Constant)	24.111	6.046		3.988	0.007			
Volunteer hours month ⁻¹ 100m ⁻²	0.356	0.053	0.669	6.745	0.001	0.863	0.940	0.492
Vegetation cover	-0.261	0.079	-0.340	-3.329	0.016	-0.673	-0.805	-0.243
Area food cultivation	0.724	0.116	0.473	6.246	0.001	0.343	0.931	0.455

74
 75 Volunteer effort exhibited the highest beta coefficient in the analysis. However, cultivation
 76 area also exhibited comparable partial and semi-partial correlation coefficients which
 77 suggested that much of the positive contribution towards overall service provision derived
 78 from genera richness 100m⁻² and volunteer activity issued from the degree of emphasis
 79 placed on food cultivation at given sites. Data on area of food cultivation was back-
 80 transformed for the purpose of interpretation. The regression equation subsequently
 81 explained that, in the case-study scenario presented here, an increase of 10% in area
 82 designated for food production led to a subsequent increase in site cumulative provision
 83 score of approximately 25%. Although this interpretation defies the allocation of an absolute
 84 value to the effect of site food cultivation extent, it gives an impression of the relative
 85 influence of urban agriculture in facilitating site delivery of ecosystem services overall. In
 86 terms of community participation, an increase in volunteer effort of 1 hour 100m⁻² day⁻¹ led
 87 to a relative increase in cumulative provision score of 10%.

88
 89 **Discussion**

90 Participatory approaches to the management of common resources in cities have been
 91 posited as a route to more resilient management of urban ecosystem services (Ernstson et
 92 al., 2008; Biggs et al., 2010; Colding and Barthel, 2013). Knowledge about how such benefits
 93 are mediated or enhance by physical characteristics of sites, and site management, is
 94 however currently lacking. The investigation into such relationships described here proved
 95 to be a valid exploration, revealing that all site characteristics studied (with the exception of
 96 food cultivation area) exhibited significant correlations with at least one other characteristic
 97 and the cumulative provision score. The analysis therefore suggests that there exist both

98 synergies to be exploited and trade-offs to be managed in civic approaches to green space
99 management.

100

101 The measure of site productivity, assessed from a spatial orientation, was negatively
102 associated with increasing site size (Figure 5), suggesting that smaller sites were more
103 efficiently productive in terms of overall ecosystem service provision. Given that cultivation
104 extent and volunteer effort were both highly influential towards total site product (Table 3),
105 it can be inferred that smaller sites more readily achieve a high level of management
106 intensity compared with much larger sites. Total volunteer input, for example, did not
107 increase proportional to site size and, being that human and community resources are finite,
108 larger sites clearly suffered from a lack of management intensity due to such limitations. As a
109 result, site size was in fact negatively correlated with volunteer input per unit area, as well as
110 with site genera richness per unit area. Social-ecological action based at small scale sites may
111 therefore be likely to provide, from a spatial viewpoint, a more efficient return in terms of
112 service provision than that occurring on a larger scale. This inverse site-size productivity
113 relationship mimics the already established, counter-intuitive, inverse farm-size productivity
114 relationship in small-holding approaches to agriculture (Alvarez, 2004), whereby smaller
115 pockets of land apparently exhibit greater productivity. The analysis also supports
116 conclusions from previous studies which have demonstrated a detrimental effect of greater
117 site size on access and area-standardised measures of participation and biodiversity in
118 collectively managed green spaces (Dennis and James, 2016). Although a multi-scale
119 approach has been adopted in research seeking more adaptive management of urban
120 ecosystems (Ernstson et al., 2010), little work has been done on the spatial aspect of service
121 delivery itself, particularly from a social-ecological viewpoint. The data analysis presented
122 herein offers insight into the on-the-ground productivity of multifunctional green commons
123 as spatially sensitive elements in social-ecological systems, a characteristic previously
124 ignored in the literature. Accordingly these findings apply to the ongoing debate over a land
125 sparing versus land sharing approach towards healthy ecosystems and ecosystem service
126 provision (Fischer et al., 2014; Stott et al., 2015), offering support to the latter model. The
127 conclusions drawn from the analysis however were based on site areas ranging between
128 200m² to 2000m² and therefore it is not clear whether the relationship observed between
129 site size and productivity holds for total land areas outside this range. Further research
130 would be required to ascertain, for example, the minimum area required for pockets of
131 green space to support ecosystem services or if the size-productivity association holds for
132 much larger urban green space types.

133

134 Site area was, particularly, negatively correlated with genera richness 100m⁻² (Table 2),
135 whereas the latter appeared to increase proportional with community input, as indicated in
136 the analysis of volunteer effort (Figure 3). This, along with the negative relationship
137 observed between vegetation cover and genera richness 100m⁻² (Table 2), describes a
138 situation which differs from the usual curve seen in species-area relationships (Rice and
139 Kelting, 1955; McGuinness, 1984) and runs contrary to general assertions in other studies
140 into the ecology of cities as to the adverse effects of urbanisation (e.g. Helden and Leather,
141 2004; Thompson et al., 2004; Godefroid and Koedam, 2007; Williams et al., 2009).
142 Accordingly, the analysis herein contradicts expectations around the effects of urbanisation
143 on biodiversity. The implication, therefore, is that, with the concerted collective
144 management of green commons, such deleterious effects can be subverted through the
145 creation of bio-diverse microhabitats. Clearly, there was a linear relationship between site
146 biodiversity and site area with the latter also being influential on volunteer input (Table 2),

147 which in turn correlated with genera richness 100m^{-2} (Figure 3). This presented a social-
148 ecological dynamic whereby, similar to expectations drawn from species-area dynamics in
149 natural systems (Gotelli and Colwell, 2001), larger sites could be expected to exhibit lower
150 species density. However the high level of anthropogenic input found at the case study sites
151 appeared to heighten this effect, the outcome being a linear biodiversity-area relationship
152 moderated by (human) community input. The situation in a social-ecological context is,
153 therefore, necessarily more complex than in more naturalistic habitats. In urban areas,
154 ecological productivity and intensification of sites in specifically urban settings is largely a
155 function of site management (Figures 2 and 3), the latter also being a factor conditioned by
156 spatial considerations (Table 2/Figure 5). Of all the case studies, the two pocket parks (sites *i*
157 and *j*), being the smallest spaces in the cohort (Table 1), appeared to exploit this dynamic to
158 greatest effect and achieved some of the highest cumulative provision scores (Figure 2),
159 largely due to the productive synergy observed between relatively smaller site size, and the
160 variables volunteer hours month⁻¹ 100m^{-2} and genera richness 100m^{-2} . Conversely, due to
161 the same processes, the relatively greater size of the community orchards in the case study
162 (sites *g* and *h*) appeared to have a detrimental effect on their overall productivity (Figure 2).

163
164 The extent of site vegetation cover had little positive impact on total service provision, and
165 in fact correlated negatively with genera richness 100m^{-2} (Table 2). This counter-intuitive
166 relationship can be explained by the fact that sites with greater vegetative extent tended to
167 be larger, an attribute which was associated with low volunteer input (Table 2). Due to this
168 effect, and perhaps as a result of type-specific management practices, larger sites were less
169 intensively cultivated and, accordingly, less diverse in terms of structure and plant genera.
170 As such, large areas of these sites exhibited low vascular plant richness and minimal
171 structural diversity. In this sense biodiversity levels in the study were subject to the same
172 pressures as seen in other appraisals of urban land-use types (e.g. Niemelä, 1999; Dauber et
173 al., 2003; Weiner et al., 2011). The difference being, however, that multi-functionality as a
174 management approach observed in this case study, when achieved to a significant degree
175 through volunteer input and an emphasis on crop cultivation, served not only to buffer
176 against the homogenisation of habitat types, but to actively increase the level of biodiversity
177 potential. The bearing of management intensity on plant genera richness 100m^{-2} is echoed
178 in the positive correlation noted between volunteer input and total provision (Figure 4).

179
180 Whereas volunteer input, genera richness and cumulative provision score all shared a strong
181 degree of synergy in the analysis (Table 2), food cultivation extent did not correlate
182 significantly with any other variables. However, the further exploration of factors influencing
183 overall site productivity, carried out through multiple regression analysis summarised in
184 Table 3 offered an alternative description of the situation. The regression analysis,
185 controlling for confounding correlations between site characteristics, revealed that genera
186 richness 100m^{-2} was not a significant contributory factor to site productivity. Intensity of site
187 management, measured as number of volunteer hours month⁻¹ 100m^{-2} and site cultivation
188 extent for food bore the strongest influence on overall site provision. Here both variables
189 exhibited comparable partial and semi-partial correlations with the cumulative provision
190 score (Table 3). The analysis therefore supports the conclusion that the product of urban
191 green space, in terms of ecosystem services, is significantly increased through community
192 participation. Furthermore, when this participation is focussed on the practice of urban
193 agriculture, the effect is heightened. These insights provide empirical evidence to support
194 more conceptual work around the benefits of urban agriculture (Viljoen et al., 2005; Mawois
195 et al., 2011; Aubry et al., 2012; Colding and Barthel, 2013), highlighting the spatial and

196 management complexities which mediate the productivity of small-scale community-led
197 agriculture. The combination of stakeholder participation and food cultivation represents an
198 important synergy which could be harnessed to ensure the optimal delivery and
199 continuation of ecosystem services in productive urban landscapes. That the proportion of
200 site area covered by vegetation connected to the ground bore a negative relationship with
201 overall ecosystem service provision (Table 3) casts doubt on the suitability of promoting
202 purely naturalistic spaces in urban areas as a panacea for social-ecological well-being as
203 previously questioned by Kowarik (2008; 2011). Similarly, this observation contributes to the
204 debate surrounding the trade-offs between facilitating public access to natural areas and the
205 associated ecological degradation which is often a result (Ewert et al., 1993; Roca and
206 Villares, 2008). The findings of this study support the idea that the increased participation of
207 stakeholders in urban green space, although potentially leading to a decrease in ecological
208 integrity, actually contributes significantly to the overall productivity of such spaces as
209 ecosystem service-providing green assets. Moreover, such participation is not universally
210 detrimental to ecological effectiveness. Particularly in areas subject to high levels of surface
211 sealing, community-led intervention can actually add ecological value by creating small
212 improvised pockets of green infrastructure. Given that productivity was inversely
213 proportional to site area, the creation of such small pockets of ecologically productive land
214 should be all the more effective. The current study therefore provides empirical evidence of
215 the social and ecological benefits issuing from community participation in urban natural
216 resource management. These benefits describe a positive feedback loop which occurs
217 between community involvement in green space management, biodiversity potential,
218 agricultural productivity and education and well-being. Further work looking at alternative
219 ecosystem services may confirm these insights and detailed research into site management,
220 perceived community benefit and sense of place could give insight as to the sustainability of
221 such positive social-ecological feedbacks.

222

223 **Conclusions**

224

225 The study revealed that certain elements of site management and design were, individually
226 and in combination, synergistic with overall productivity in terms of ecosystem services.
227 Specifically, the work provides evidence to support the potential benefits of small-scale
228 community-led agriculture in urban areas. Encouragement is also provided for the possibility
229 of collaborative groups to generate urban-relevant ecosystem services in areas of minimal
230 ecological interest in cities. The suggestion of an apparent inverse site-size productivity
231 relationship in the analysis may contribute to the debate over the relative gains of land
232 sharing versus sparing towards maximum provision of ecosystem services in the urban
233 environment. Further work may serve to identify thresholds in such spatial trends and clarify
234 the need to complement small-scale cultivation of urban green space with larger natural
235 spaces in order to enhance landscape-scale ecological diversity and target alternative
236 ecosystem services to the ones examined in this study. Notwithstanding these uncertainties,
237 collaborative approaches to environmental stewardship in urban areas could, by enhancing
238 positive feedbacks between management, design and participation, present an effective
239 governance tool towards adaptive, productive social-ecological systems and provide
240 examples for green space management in the wider landscape.
